the anterior border of the anal sphincter complex (3.47 cm). *Abbreviations*: S, symphysis pubis; U, urethra; B, bladder; R, rectum; A, anus; L, levator ani muscle.

ULTRASOUND IMAGING AND SURGERY FOR URINARY INCONTINENCE AND PELVIC ORGAN PROLAPSE

The role of US imaging during and after incontinence surgery has been investigated. Researchers have tried to standardize the amount of bladder neck suspension during the Burch procedure and to correlate the relative position of urethral slings and the urethra with the outcome of surgery. Actually, no definitive conclusions can be drawn on the relation of sling position, resolution of POP rather than UI, or postoperative complications [172,188–196,251]. In some studies, tension-free vaginal tapes were found to be positioned more cranially compared to transobturator tapes and caused more urethral kinking during straining; nevertheless, comparable cure rates were achieved [197,198]. US imaging is clearly superior as compared to other imaging techniques regarding the visualization of polypropylene mesh materials (Figure 37.19) as used in POP and UI surgery, and it had been also successfully employed to correlate vaginal anatomical and functional changes following colpocleisis surgery [252]. US also demonstrated a change in levator hiatal biometry following POP repair, revealing a reduction in hiatal area but no changes in hiatal distensibility [253]. Various studies have recently explored the causes of POP relapse, such as mesh dislodgment or preoperative LAM avulsion, but no conclusive data have been obtained yet [199–201,254]. In this field, MRI has been evaluated as a promising technique [255,256]. The use of MRI has proven to be of certain value in evaluating the outcome of surgery, but only as regards the apical compartment, no correlation among MRI imaging, POP-Q, and symptoms was observed [257]. US imaging of bulking agents injected for SUI (Figure 37.20) showed a good correlation between the height and volumes of the injected collagen bulges and clinical outcome, with a collagen volume of 2.8 mL considered to be ideal [202,203].

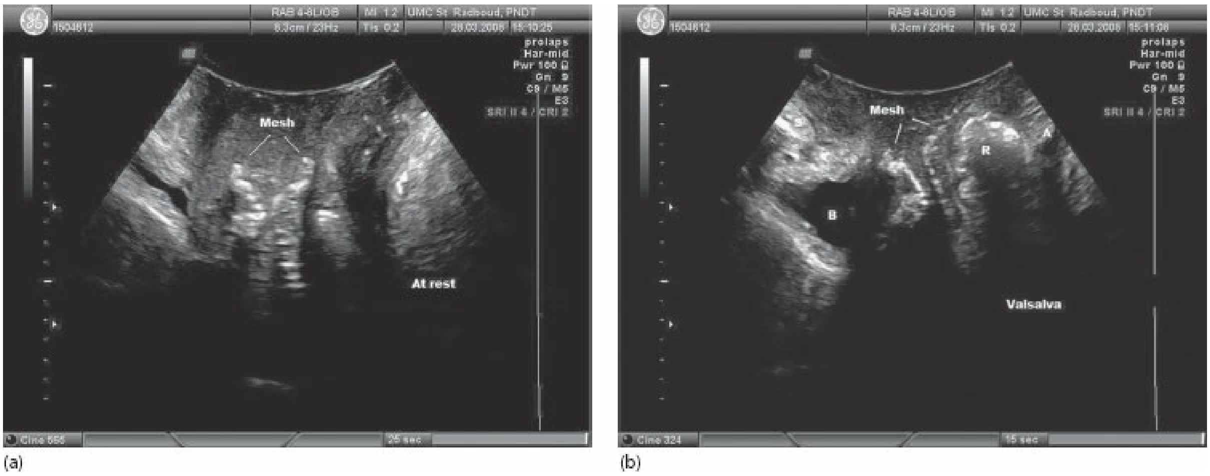

Figure 37.19 Perineal midsagittal two-dimensional view at rest (a) and on Valsalva (b) in a woman with polypropylene mesh (prolift anterior and posterior). *Abbreviations*: S, symphysis pubis; B, bladder; R, rectum; A, anus.

CONCLUSIONS

Research into US imaging of the pelvic floor in UI and POP continues to be active and the quality of the published data was increased significantly over the last decade. Imaging is a powerful tool for research into UI and POP pathophysiology. Both US and MRI proved to be comparable to physical examination and sometimes superior although this rarely translates into a real clinical benefit. Research in this area has proved to be inventive, innovative, and prolific thanks to a widespread use of US systems in urological and urogynecological offices. The evidence currently available should be carefully scrutinized to identify areas of consensus and areas that still need further verification and confirmation. The lack of proven clinical utility should not reduce our research efforts and imaging is a powerful approach to improve our understanding of LUTDs.

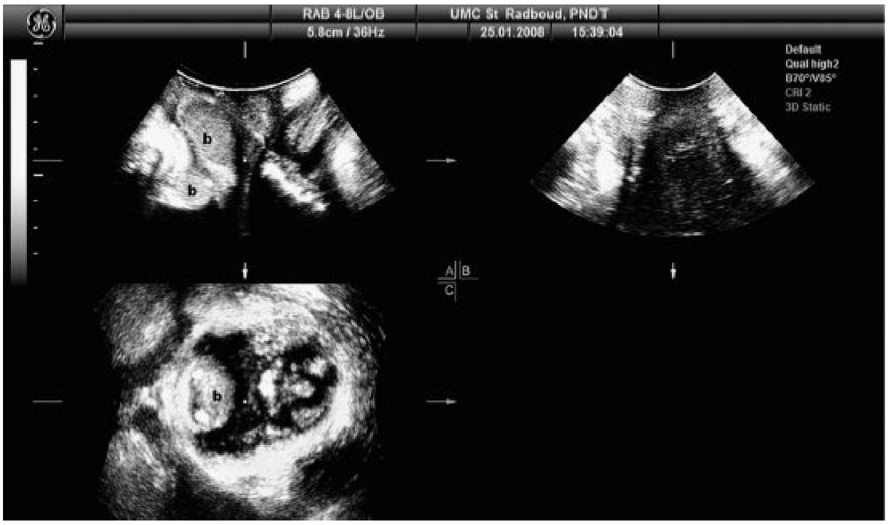

Figure 37.20 Perineal ultrasound imaging in a woman following periurethral bulking agents for stress urinary incontinence. Midsagittal (left upper), coronal (right upper), and axial (left lower) two-dimensional view. *Abbreviation*: b, periurethral bulking agent.

38 Magnetic Resonance Imaging in Urogynecology

Elisabetta Costantini and Marcus J. Drake

INTRODUCTION

True insight into the mechanisms underlying pelvic organ prolapse (POP), urinary incontinence, and fecal incontinence requires an appreciation of the pelvic anatomy, including the muscular and ligamentous mechanisms. These relationships in the asymptomatic population, and the deficiencies seen in symptomatic women, require an approach able to assess the anatomical relationships both in a static situation and also when undergoing physical stress. Cross-sectional imaging is able to achieve this and gives valuable insights from which our current knowledge-base can be developed. In addition, for individual patients, MRI scanning can offer supplementary information as needed for diagnostic understanding with a view to treatment. MRI has shown rapid technical development in recent years, and it is now able to offer detailed insights using a range of protocols and modalities, in combination with physical manipulations of the scan subject. Such progress is invaluable for understanding female pelvic floor anatomy for populations and individuals, understanding the changes evident in symptomatic situations, identifying women potentially at risk of future problems, and understanding impact of past events, such as childbirth or surgery.

MRIs map 3-D anatomy, which is generally displayed in standard orientations (coronal sections, sagittal sections, or transverse sections). With MRI, it is possible to see the individual lower urinary tract and genital structures, the individual muscles of the pelvic floor, and the bony structures. Furthermore, additional post-imaging processing can focus on specific aspects of interest and potentially display the anatomy in three dimensions. Comparisons between MRI and formal anatomical dissection in cadaveric specimens [1] have served as a validation supporting the conclusions of MRI findings.

MRI was generally used statically in specific situations, such as investigation of urethral diverticula. This is now augmented with dynamic imaging, in which a series of scans are obtained at rest and during movement or function (e.g., squeezing, straining, or defecation). This is especially contributory for preoperative assessment of patients with multicompartment POP defects and failed surgical POP repairs. Not only is MRI an indispensable tool for clinical decision making, but it also has tremendous potential as a research tool in trying to understand the pathophysiology of these complex disorders [2].

MRI Methodology

MRI scanning uses strong magnetic fields and radio waves, without the involvement of ionizing radiation. A strong magnetic field is placed around the subject, and the scanner detects a radiofrequency signal emitted by excited hydrogen atoms. The strength of the magnetic field is measured in tesla units, with most MRI systems currently operating at 1.5 T. Increased magnetic strengths are commercially available, and the technological development means magnetic field strength is likely to evolve foreseeably. Stronger magnets currently require superconduction in very cold temperatures (liquid helium). Permanent magnets can also be used to generate weaker fields, and these have the potential to create a non-enclosed MRI scanner.

Contrast between different structures is ascertained from the rate at which excited atoms return to the equilibrium state. The nature of return to the equilibrium state involves two independent processes of T1 (spin–lattice) and T2 (spin–spin) relaxation. T1 is basically representative of the different amounts of magnetization recovery, which is achieved by changing the repetition time. T2 is the difference in magnetization decay and is achieved by changing the echo time. Distinguishing T1 and T2 gives different imaging displays that may enhance detection of specific aspects, and both approaches are typically used in scanning protocols. For example, T2 is good for detecting edema and for assessing zonal anatomy, such as in the uterus. Contrast agent, comprising gadolinium and a chelating agent, can also be administered intravenously.

Static sequences are obtained mainly using T2-weighted axial and sagittal planes. Dynamic sequences use single-slice ultrafast acquisitions during the tested activity, in coronal and axial planes (Figures 38.1 and 38.2). The T2-weighted sagittal sequences are useful to show the bladder neck and the cervix. Sagittal acquisitions help to adjust coronal images by identifying the midline of the pubic symphysis and the anatomical landmarks. Coronal planes explore dynamic physiology of the levator muscles. Measurement of the urogenital hiatus and detection of levator ani injuries can be performed in axial plane images [3].

Imaging Protocols

There are many protocols for MRI scanning. A specific approach has been described for female pelvic MRI acquisition [4,5]. Before scanning, the patient is asked to empty her bladder and she should have clear explanation of what to expect, including instructions in any dynamic maneuvers that may be required, e.g., straining. A multicoil array is placed in position, reaching sufficiently inferior that any POP is fully captured. A standard axial fast spin echo sequence is taken to achieve high-resolution axial images of the pelvic organs, muscles, and supporting connective tissues.

For dynamic imaging, a midline slice should include the symphysis, bladder neck, vagina, rectum, and coccyx. If necessary, two contiguous locations may be specified where it is not possible to fit all structures into a single imaging slice. The patient is then asked to strain at maximum effort. T2-weighted imaging of the sagittal midline images is then obtained with image acquisition aiming to take less than 3 seconds. Dynamic MRI is generally done with the patient supine and with her thighs flexed. Dynamic MRIs with opened antennas are now available to realize the acquisitions in a standing or a sitting position (e.g., with defecation). Nonetheless, it is not certain that imaging in a standing position improves its relevance [3].

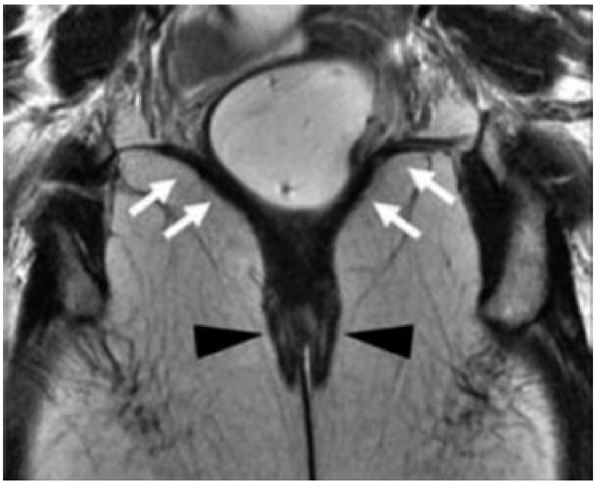

Figure 38.1 MRI of normal female pelvic anatomy in the coronal plane. There is normal thickness and symmetry of levator ani, iliococcygeus, and pubococcygeus muscles (white arrows), which align with puborectal muscle fibers of the anal sphincter (black arrowheads).

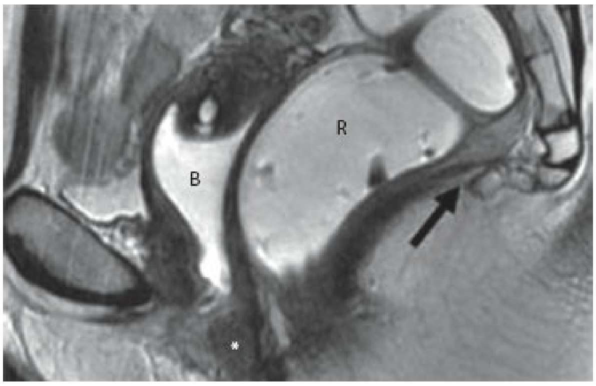

Figure 38.2 MRI of normal female pelvic anatomy in the axial plane. The puborectalis muscle forms a sling around the rectum. Posteriorly, the fibers fuse anterior to the coccyx to form a midline structure, the levator plate (arrow). *, perineal body; B, bladder; R, rectum.

Imaging Artifacts

MRI scan images are captured in a sequence of “slices,” taken in parallel along a line related to the scanned subject. The relationship to the subject can be varied, but there is a risk of errors in linear and angular measurements, termed “slice angle errors.” Accordingly, accurately ascertaining linear measurements on 2-D images requires a standardized and consistent approach between subjects, or conversion to a 3-D image from which to take measurements.

“Chemical shift” artifact is a separate problem that can cause apparent discrepancy in size for equivalent structures on opposite sides of an axis. As a consequence, within subject comparisons of dimensions for different sides may be unreliable, and between-subject comparisons invalid, unless the scanning parameters are set up appropriately and maintained consistently throughout the entirety of data acquisition.

Safety

The strength of magnetic field means that MRI is contraindicated in the presence of cardiac pacemakers, cochlear implants, and some other surgical implants. The presence of any internal metal fragments, body-worn metal (jewelry), or stray metal objects in reach of the magnetic field also have to be excluded for the safety of the patient and the scanner.

The patient undergoing scanning is placed in a confined environment, and this is problematic for patients prone to claustrophobia. Careful support for such patients and use of suitable medications according to hospital practice may be warranted. Permanent magnets have the potential to create an open (non-enclosed) MRI scanner that might be helpful in situations where a patient cannot tolerate a confined space.

Gadolinium side effects may include headache, nausea, and temporary dizziness in 1%–5%. A feeling of coldness may occur at the injection site. Anaphylactic reactions occur in about 1 in 10,000 people. Gadolinium contrast medium should be avoided in patients with kidney disease (chronic or acute). Case reports of nephrogenic systemic fibrosis, leading to skin contractures and organ failure, have been described with gadolinium contrast in a minority of patients with preexisting severe renal dysfunction.

For women in the first trimester of pregnancy, safety is uncertain, but it may be preferable to alternative options [6,7].

MRI CHANGES IN SYMPTOMATIC WOMEN

Alterations in the vaginal shape can clearly be demonstrated in women with POP using MRI [8]. T1 signal intensity can identify muscle atrophy in women with stress urinary incontinence (SUI) [9]. The likelihood of a role for levator weakness can be appreciated in women with SUI, and such laxity and thinning of the levator ani muscle in SUI have been reported [10]. However, it is likely that there is degree of overlap between symptomatic women and asymptomatic nulliparous women [11]. In women with SUI, the bladder neck lies close to the pubic symphysis, the lumen of the vagina has a widened H-shape, and the urethropelvic ligaments are near horizontal. The urethropelvic ligaments were reported to attach to the lateral aspect of the urethra to the medial aspect of the levator sling [12].

For some symptomatic women, bony changes may be evident: the transverse inlet can be wider, the intertuberous and interspinous diameters can be increased, the sacral length can be increased with a deeper curve, and the anteroposterior outlet can be narrowed [13]. The technology for 3-D imaging continues to develop, and progress in understanding clinical anatomy of the levator ani and bladder neck [4] will continue. For example, 3-D reconstruction has been undertaken to compare asymptomatic women with women found to have urodynamic stress incontinence or symptomatic POP [5]. The latter study reported the levator–symphysis gap as a marker for disruption of the attachment of the anterior puborectalis attachment.

The urethra can be imaged effectively using MRI. For example, urethral diverticula can be visualized clearly (Figure 38.3a through d). In addition, placement of an MRI coil vaginally can demonstrate the periurethral and perivaginal connective tissues [14] and the location of the striated urethral sphincter [15].

Puborectalis is uniformly intact in nulliparous women [16] (Figure 38.4a). In primiparous women, around 20% have some degree of structural defect or deviation (Figure 38.4b and c). If a disruption is present at the attachment to the superior pubic ramus, there is a high prevalence of SUI [16]. Such disruptions correspond with a reduction in maximum urethral closure pressures (MUCPs), associated with reduction in the voluntary increment in MUCP during pelvic floor muscle contractions [17]. Taken together, these findings would suggest that vaginal childbirth may weaken the urethral closure mechanism, thereby disposing the patient to urinary incontinence.

MRI in asymptomatic nulliparous women shows some structural differences between African-American and Caucasian-American women, which may be relevant to potential for subsequent development of pelvic floor problems. Nulliparous African-Americans have significantly thicker levator ani muscles [18] and a higher urethral volume [19]. Functionally, they have higher resting and squeezing MUCPs in comparison to the Caucasian women.

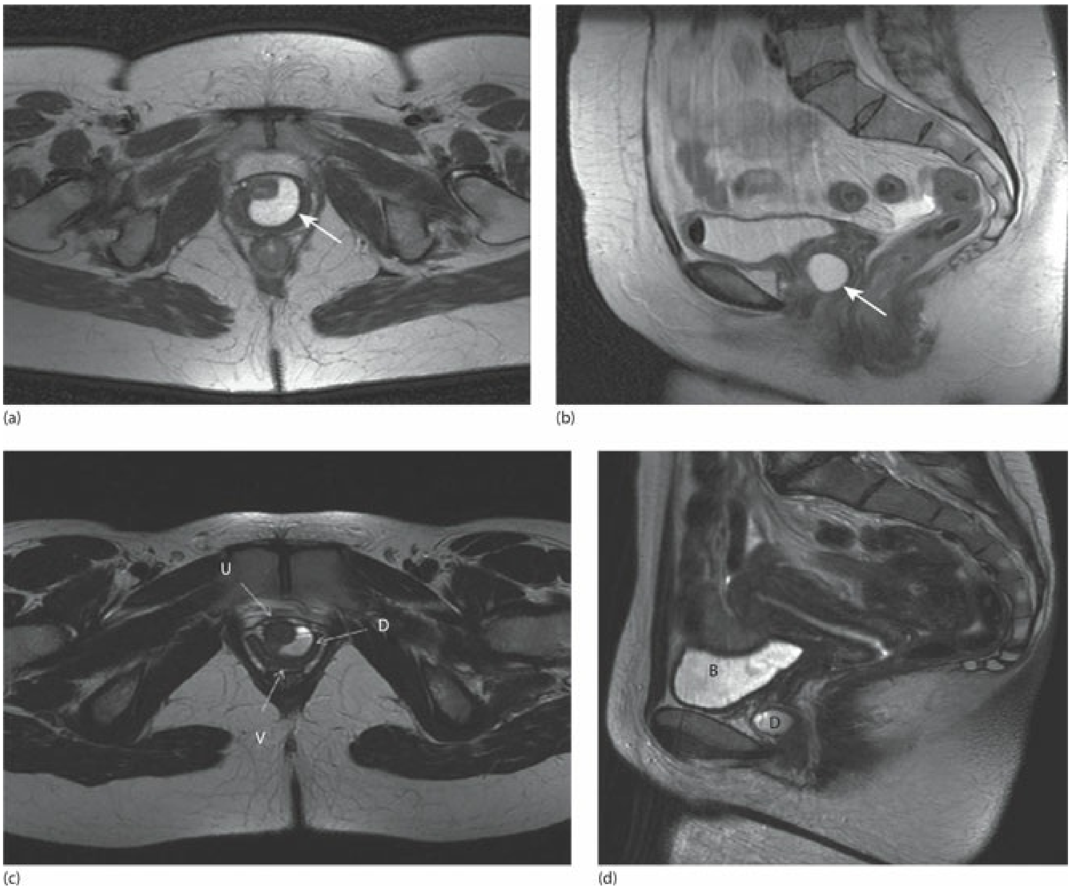

Figure 38.3 MRI in female patients with urethral diverticula. (a, b) Case 1: (a) the diverticulum (arrow) in the

transverse plane; (b) same case in the sagittal plane. (c, d) Case 2: (c) the diverticulum in the transverse plane; (d) same case in the sagittal plane. B, bladder; U, urethra; D, diverticulum; V, vagina.

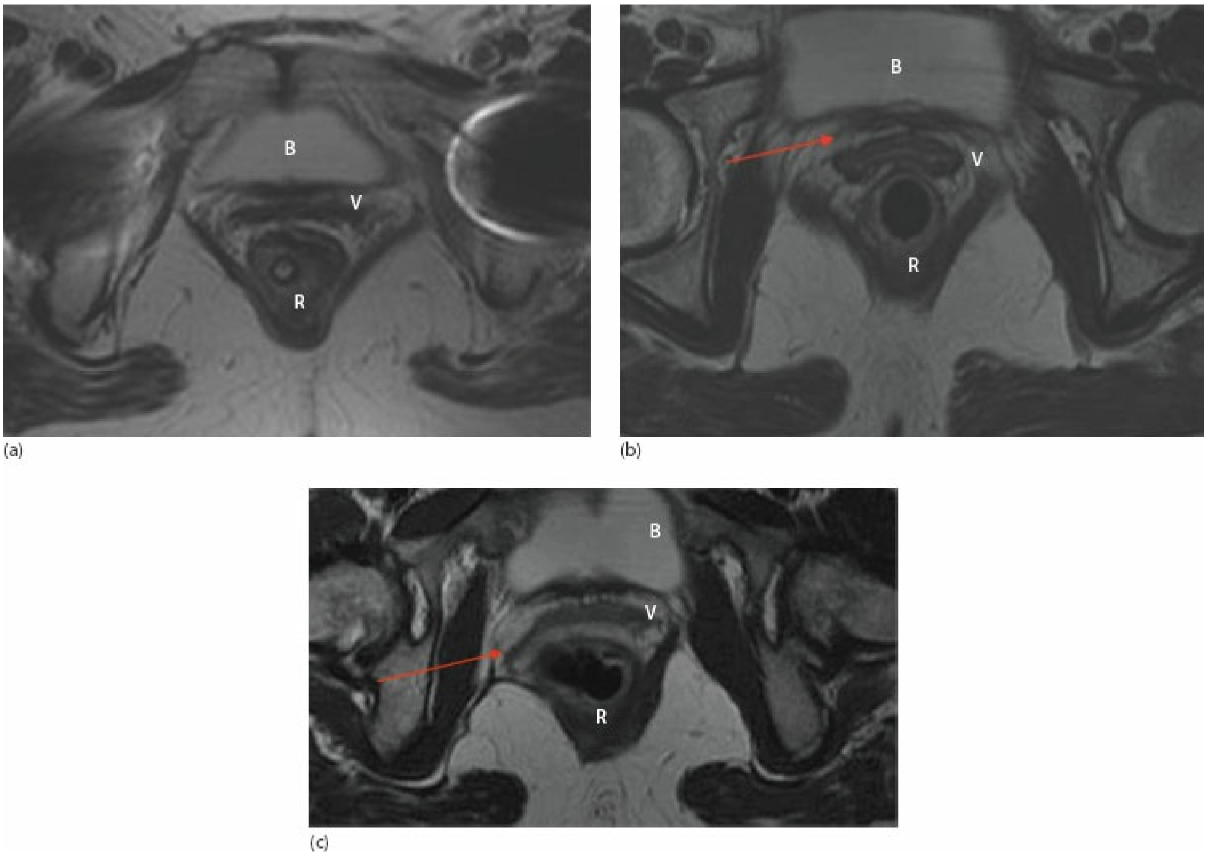

Figure 38.4 MRI images of vaginal anatomy. B, bladder; V, vagina; R, rectum. (a) Normal vaginal anatomy. (b) Mild fascia lateral defect (red arrow). (c) More severe fascia lateral defect (red arrow), with deviation of the posterior vaginal fornix.

Dynamic MRI has enhanced the understanding of pelvic floor anatomy and dysfunction. It has the advantage of detailed anatomical views of all three compartments at rest and during Valsalva. Several attempts to standardize MRI measurements have been made. Five midsagittal pelvic reference lines have been employed to quantify prolapse using MRI and used to measure the extent of prolapse [20]. The pubococcygeal line (PCL) (Figure 38.5), which is thought to approximate the plane of the levator plate, is the most widely used reference line for assessing POP, with an excellent intra- and interobserver reliability. It is a straight line between the inferior border of the pubic symphysis and the last coccygeal joint. The distance from the PCL to the bladder neck, cervix, and anorectal junction should be measured on images obtained when the patient is at rest and during maximal pelvic strain. MRIs allow us to obtain a contemporary visualization of different compartment defects [21] (Figures 38.6). In healthy volunteers, there is minimal movement of the pelvic organs with respect to the PCL, even during maximal strain [2]. Other parameters are the H-line, from the inferior border of the symphysis to the posterior wall of the rectum at the level of the anorectal junction, and the M-line, which goes perpendicularly from the PCL to the most posterior aspect of the H-line (Figure 38.5). The H- and M-lines tend to elongate with pelvic floor relaxation. With these landmarks, it is possible to standardize and to grade the prolapse severity. However, the concordance of measurements made with MRI with those made using clinical examination seems poor [22]. Hypotheses for this variability are the differences in the patient's position (dorsal lithotomy during MRI versus gynecological position during clinical examination), a different coactivation of the levator ani between MRI and clinical examination, and the use of a speculum in gynecological examination.

Betschart and colleagues have proposed a new standardized approach called the pelvic inclination correction system (PICS) [20]. Based on bony structures and the body axis, the PICS corrects for variation in pelvic inclination, at rest or straining, and allows for the standardized measurement of organ displacement in the direction of prolapse. It is widely recognized that the angle of pelvic inclination can change during specific maneuvers such as the Valsalva and Kegel maneuvers. This angle can also be affected by the way that an individual lies in the scanner (e.g., with knees supported versus legs extended). The optimal pelvic reference system should allow the investigator to compensate for these variations.

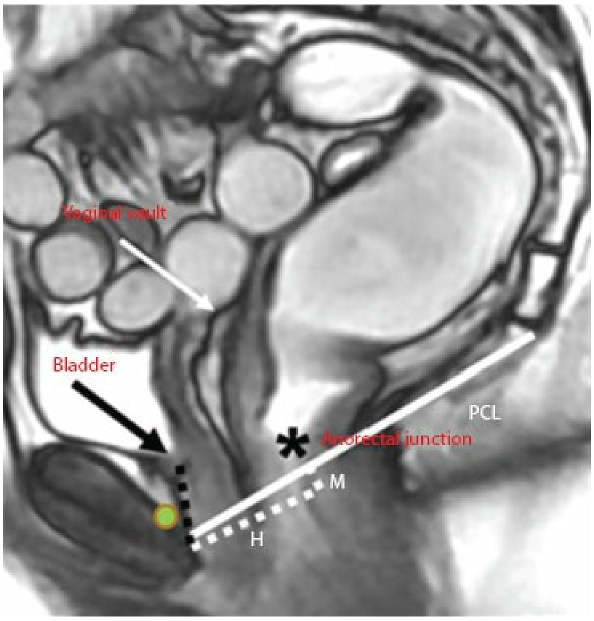

Figure 38.5 The most commonly used reference lines in female pelvic MRI. The *pubococcygeal line* (PCL), from the inferior border of the pubic symphysis to the last coccygeal joint. All the distances from PCL (bladder neck, cervix, and anorectal junction) are measured at rest and during maximal pelvic strain. The*H-line*, from the inferior border of the symphysis to the posterior wall of the rectum at the level of the anorectal junction. The*M-line*, perpendicularly from the PCL to the most posterior aspect of the H-line. The *green circle* denotes the urethral axis, which is vertical during straining and defection.

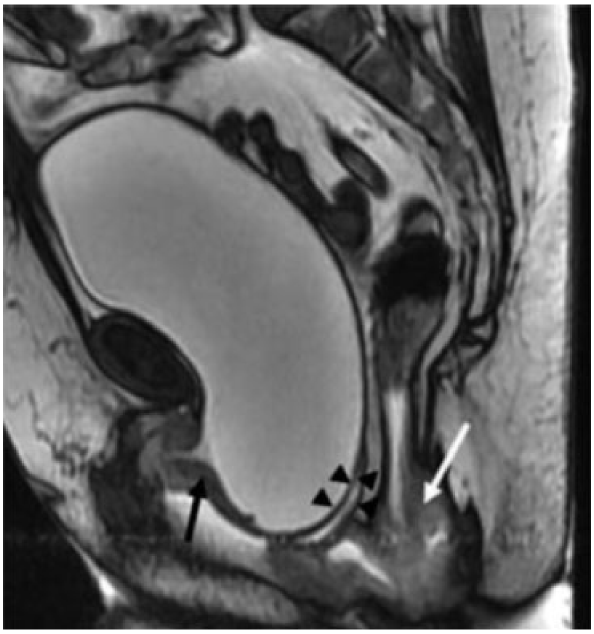

Figure 38.6 Large cystocele with urethral kinking (black arrow), which contributes to inefficient bladder emptying. The vagina is filled with sonographic gel (arrowheads); intra-anal full-thickness rectal invagination

(white arrow) at the level of the anal canal, thus impeding stool passage.

ADDITIONAL POSSIBILITIES WITH MRI

Magnetic Resonance Defecography

Defecatory dysfunction and fecal incontinence may result in the presence of impaired support due to rectocele or a deficient perineal body, or physical impedance as a consequence of POP. When the patient does abdominal straining, the additional pressure and altered organ positions may worsen the symptomatic issues. Intrinsic bowel issues, such as rectal prolapse or intussusception, are another substantial factor. MR defecography is a method for elaborating underlying issues of this type [23]. Contrast in a suitable medium is placed into the relevant body cavities, images at rest are obtained, and the patient is then instructed to undertake relevant physical activities to highlight the anatomical features during high speed scanning, ideally in the upright position.

MR defecography has an important role in the definition of particular situations involving the posterior compartment. Sagittal images during defecation can be used to recognize and differentiate an anterior or posterior rectocele (Figure 38.7a and b). The difference between rectal mucosal intussusception and rectal full-thickness intussusception can only be inferred at conventional defecography (Figure 38.8a and b), and it is relevant, as the treatment for the two conditions is different. Furthermore, in the case of enterocele, MRI can identify the content of the peritoneal cul-de-sac (Figure 38.9a and b), which may be fat or bowel loops. Using MRI, it is also possible to recognize particular situations that may be difficult to diagnose only by clinical examination (Figure 38.10).

MRI in Postoperative Evaluation

Another application of MRI is the evaluation of complications or recurrence after POP repair. Dynamic MRI can verify the effectiveness of support of anterior and posterior pelvic floor structures, for example, after placement of polypropylene mesh implants. Postoperative dynamic MRI might also be helpful to understand the development of recurrent POP and to support its early detection. Siegmann and colleagues [24] demonstrated that dynamic MRI could detect clinically occult cases of POP 3 months after pelvic floor repair in 73% of the cases. These postoperatively detected pelvic floor dysfunctions are probably caused by preexisting multicompartment defects that were not detected in the preoperative clinical evaluation. POP due to defect in one compartment may suppress the symptomatic detection of a defect of another pelvic floor compartment. Hence, symptoms from another POP may be detectable once the leading pelvic floor compartment has been repaired. However, these occult recurrences did not correspond to clinical symptoms on short-term follow-up (3 months), so their diagnostic relevance has yet to be established. Notwithstanding, it is possible that dynamic MRI can reliably identify POP after pelvic floor repair before the onset of symptoms [24].

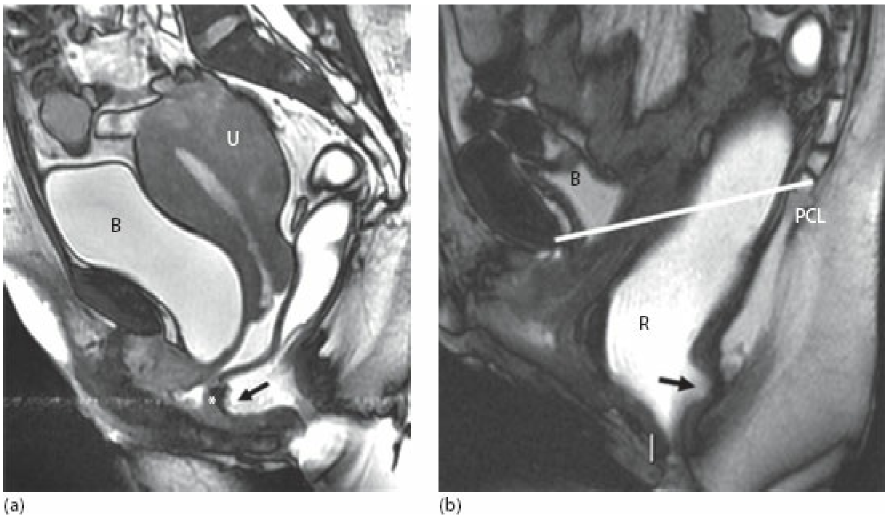

Figure 38.7 Posterior compartment. (a) Sagittal images during defecation. B, bladder; U, uterus; R, rectum; PCL, pubococcygeal line. Anterior rectocele is evident as an outpouching of the anterior rectal wall (arrow),

with stretching of the perineal body (*) and protrusion of the rectum into the vaginal lumen. (b) Severe perineal descent, incomplete opening of the anal canal and appearance of a small posterior rectocele (arrow).

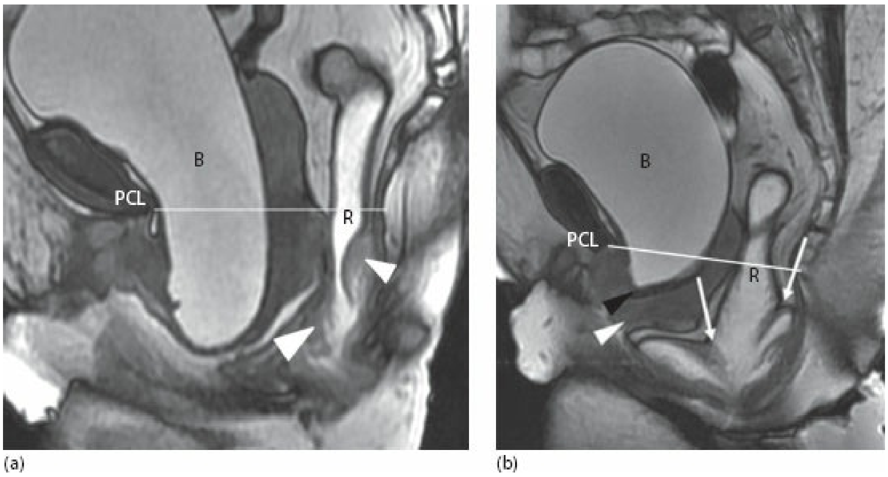

Figure 38.8 (a) Rectal mucosal intussusception. During defection, abnormal thickening and redundant infolding of the mucosal layer in the posterior and anterior rectal wall (arrowheads). Mucosal infolding occupies the rectal lumen and obstructs normal passage of stools. There is associated anterior and middle compartment prolapse. B, bladder; R, rectum; PCL, pubococcygeal line. (b) Intrarectal invagination (arrows). The invagination obstructs the rectal lumen causing intrarectal residue after defecation. Cystocele (black arrowhead) and cervical prolapse (white arrowhead) are associated. B, bladder; R, rectum; PCL, pubococcygeal line.

Several studies used dynamic MRI to investigate prolapse correction after sacrocolpopexy. MRI can be used not only to investigate clinical outcome but also to investigate postoperative pain or recurrent symptoms of prolapse by assessing suspected mesh infection, lumbosacral osteomyelitis, and integrity of mesh attachment [25].

Dynamic pelvic MRI is particularly useful to evaluate bowel dysfunction, as well as urinary stress incontinence, urgency, or retention. For example, when the posterior mesh is too short or is fixed with too much tension, the patient may complain of dyschezia or anal pain [26].

3-D Female Pelvic Floor Reconstruction

Computed integration of the image stacks can be used to extrapolate 3-D reconstructions of the subject anatomy. For female pelvic floor image reconstruction, specified structures (e.g., the component lower urinary tract or genital tract organs) are separately identified, which requires a combination of manual and semiautomated processing. Their surfaces are then rendered, i.e., the “gaps” between the respective organs in the successive slices are filled. Color-coding can be used to distinguish between specific structures. Variations in the color can also be used to portray additional facets, such as the altering thickness of muscle [27] or the bladder wall thickening in the presence of bladder tumors [28].

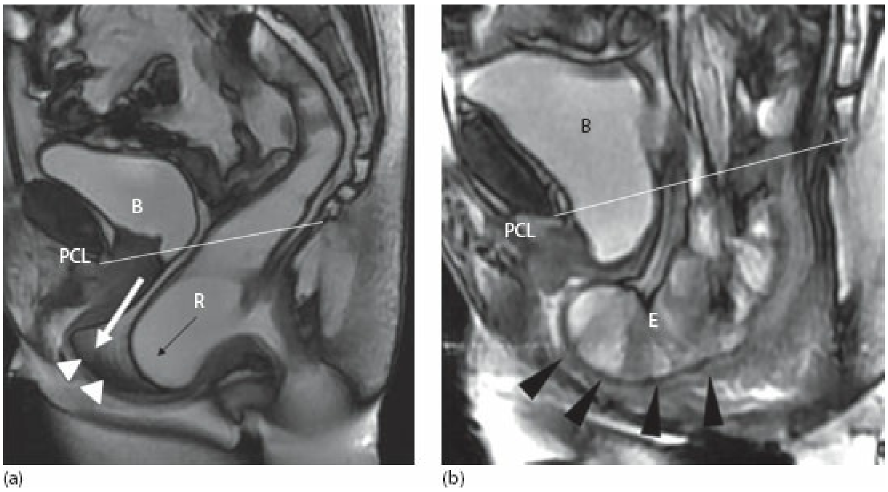

Figure 38.9 Enterocele MRI image. (a) Large anterior rectocele (black arrow). A peritoneal cul-de-sac (white arrows) herniating into the rectovaginal space, with a large fat-containing enterocele. B, bladder; R, rectum; PCL, pubococcygeal line. (b) In this case, at late defecation the rectovaginal space is occupied by a large enterocele (arrowheads). Rectocele and cystocele are contemporary present. B, bladder; E, enterocele; PCL, pubococcygeal line.

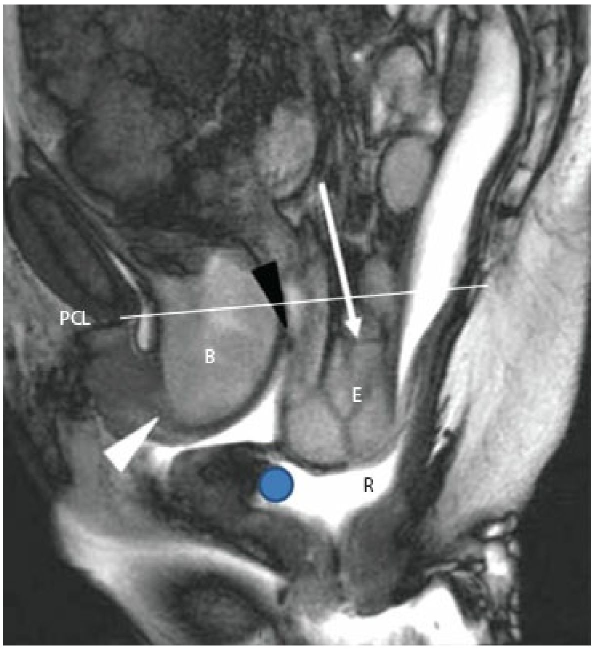

Figure 38.10 Cystocele (white arrowhead) and vaginal vault prolapse (black arrowhead) are present and associated with a large enterocele (E) that closes the rectal lumen causing obstructed defecation and incomplete emptying of the anterior rectocele (blue circle). B, bladder; R, rectum; PCL, pubococcygeal line.

Correspondence of data taken from a 3-D reconstructed structure with functional data measured in the same patient provides some validation of the processing. For example, volume data measured from 3-D image reconstructions of the external anal sphincter in nulliparous women correlate with the length of the high-pressure zone at squeeze in anorectal manometry [29]. The 3-D reconstructions can be used for planning surgical interventions, facilitating the surgeons' mental assimilation of the surgical anatomy in a quicker and more intuitive way than "scrolling" back and forth through the image stack.

A progression of the method is to simulate what might occur in particular events. For example, a simulation of childbirth using MRI of the bony pelvis and levator ani, and simulated passage of a fetal head shows the likely extent and location of stresses in the muscle [30] and that the strength of levator ani attachment could influence the extent of muscle stretch [31].

It is important to recognize that the reconstructions do not offer additional imaged information since the only patient-derived data come from the image stack; the 3-D reconstruction comes from assumptions delivered by computed algorithms that rely on the successive images in the stack being sufficiently close together to give adequate representation.

CONCLUSIONS

MRI gives a considerable amount of anatomical information, with some ability to observe pathological processes such as edema and inflammation. Techniques to generate new approaches to displaying the output have given extra opportunities to improve application of imaging in real-life contexts. Further technological developments offer new opportunities to understand how physical stresses affect structure and potentially relate to function.

39 Endoscopy

Musaab Sarmad Yassin, John Michael Henderson, and Francis Xavier Keeley

INTRODUCTION

Endoscopy refers to the use of a telescope to directly visualize an internal structure or organ. It may be used in the evaluation of a patient with urological symptoms and demonstrate abnormalities such as malignancy, calculi, diverticula, or fistulae. Urethroscopy, cystoscopy, ureteroscopy, and renoscopy refer to endoscopy of the urethra, bladder, ureter, and kidney, respectively.

Endoscopy requires a light source, irrigating fluid, and endoscope (Figure 39.1). A camera is usually applied to the endoscope head to allow ergonomic use of the equipment. The irrigant fluid allows distension of the bladder and removal of blood or debris to allow a clear view. The most common fluid used is warmed 0.9% saline or sterile water. If electrocautery is planned, a nonconducting solution such as 1.5% glycine is required. Light is delivered to the tip of the endoscope via noncoherent fiber bundles demonstrating total internal reflection. The light source used is usually xenon, which is more expensive and a neutral tone, or halogen, which is cheaper, is a more yellow tone, and requires a white balance.

HISTORY

Urological diseases have been prevalent throughout the ages. Historical treatments for these diseases were often crude and delivered without asepsis or anesthesia. The lithotrite was an instrument inserted blindly into the male urethra to attempt to crush bladder calculi.

Developments in lens and light technology led to significant improvements such as the Nitze–Leiter cystoscope in 1879 [1].

A further revolution in design was achieved by Harold Hopkins, Professor of Physics at the University of Reading. His “rod-lens” system was a tube of glass with thin air lenses that replaced the traditional air tube with glass lenses. Karl Storz developed a system of transmitting cold light from an external source through noncoherent fibers to provide illumination. Their collaboration in 1966 produced a dramatically improved instrument of smaller diameter with a better image.

TYPES OF ENDOSCOPE

Urological endoscopes can broadly be divided into rigid, semirigid, and flexible scopes. Rigid telescopes employ the Hopkins rod-lens system by which light is transmitted to illuminate the target and the image is returned to the eyepiece. Various angles of telescope allow optimal visualization of parts of the urological tract. Zero-degree telescopes are ideal for urethroscopy, whereas cystoscopy requires a 12° or 30° scope. A 70° telescope allows the bladder neck to be thoroughly inspected. An offset eyepiece, as employed with nephroscopes, allows the introduction of straight instruments, e.g., ultrasonic or pneumatic lithotripsy. A semirigid endoscope allows a small degree of flexibility but is rigid enough to retain the advantages of a rigid endoscope.

Cystoscope sizes are expressed in French (Fr) that refers to the external circumference in millimeters. Rigid cystoscopes are available in a number of different sizes (e.g., 22F or 26F) that allow passage of instruments to resect bladder tumors (resectoscope) or crush bladder calculi (lithoclast). The larger caliber of the irrigation channels in a bigger endoscope improves flow and vision when blood or debris is present in the bladder.

Flexible endoscopes have two bundles of optic fibers, which facilitate illumination (noncoherent) and image (coherent) transmission. Two control wires deflect the tip 270° each way (Figure 39.2) making complete maneuverability possible [2]. These flexible materials do not resist temperatures in an autoclave, so decontamination, rather than sterilization, is used to clean them. The slower flow through this narrower caliber instrument may make clear visualization more difficult than in a rigid instrument. An instrument channel is present to allow passage of guidewires, needles, and forceps. The use of this channel may further hinder irrigant flow.

INDICATIONS

Specific situations where cystoscopy should be considered include the presence of hematuria or significant past medical history. Cystourethroscopy is not routinely indicated in the assessment of a patient with lower urinary tract symptoms alone. Blood in the urine (hematuria) may be divided into visible (macroscopic or *frank* hematuria) or nonvisible (microscopic or using dipstick urinalysis) and is an indication for cystourethroscopy to diagnose an underlying condition, such as bladder cancer. However, if there is only a trace of blood on dipstick, it may be discounted without undertaking endoscopy [3]. The past medical history should be reviewed; for example, a woman with new-onset storage urinary symptoms, leukocyturia, and a past history of a difficult placement of a midurethral tape may need cystoscopy to exclude tape exposure.

Certain urological symptoms are strong indicators of specific pathology. The passage of air (pneumaturia) or feces (fecaluria) in the urine strongly suggests a colovesical fistula, and cystoscopy may reveal inflamed urothelium around the site of the fistula. Continuous incontinence may result from a vesicovaginal fistula or ectopic ureter bypassing the urinary sphincter. Postvoid dribbling in the female can indicate a urethral diverticulum (UD), the opening of which may be visible at urethroscopy.

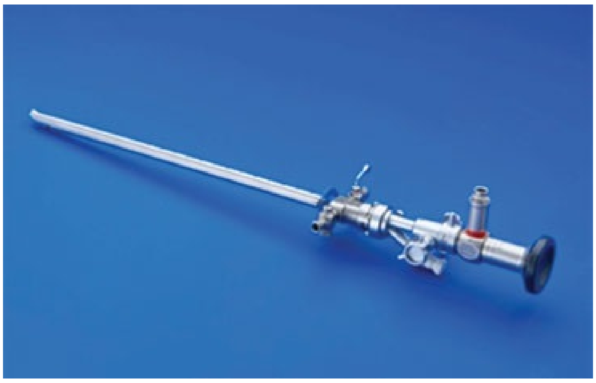

Figure 39.1 Rigid cystoscope. (Courtesy of Karl Storz Endoscopy, Culver City, CA.)

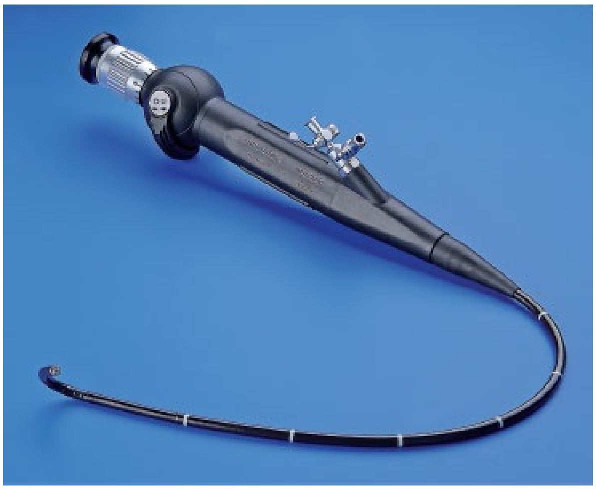

Figure 39.2 A flexible endoscope. (Courtesy of Karl Storz Endoscopy, Culver City, CA.)

Cystourethroscopy is indicated after mesh insertion to ensure that the bladder or urethra has not been inadvertently perforated (Figure 39.3).

CYSTOURETHROSCOPY

Informed consent should be obtained and appropriate antimicrobial prophylaxis administered according to local practice. The cystoscope should be assembled correctly and connected to sterile irrigant fluid at approximately 90 cm above the patient's pubic symphysis. If a halogen light source is used, a white balance should be performed. Lubrication of the urethral meatus with an anesthetic gel is followed by gentle passage of the cystoscope, following the lumen of the urethra.

A thorough and systematic inspection of the urethra and bladder is always required. Identification of the ureteric orifices at the apex of the trigone is followed by careful inspection of the lateral, posterior, anterior walls, and bladder neck (for which a 70° or flexible endoscope is required). The bladder may have muscular ridges (trabeculations) or outpouchings (diverticula) that suggest outflow obstruction (Figure 39.4).

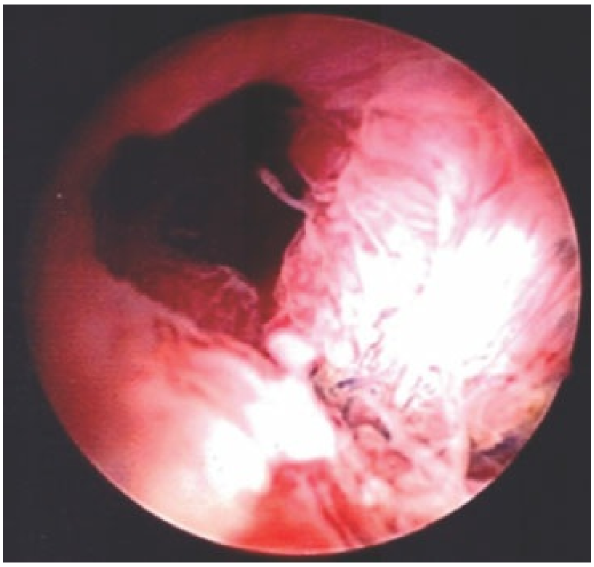

Figure 39.3 Mesh seen in urethra following treatment for stress incontinence.

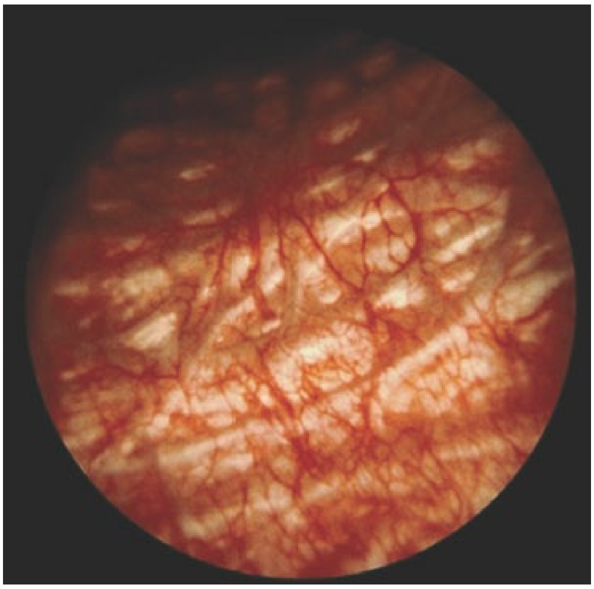

Figure 39.4 Bladder trabeculation; thickened ridges on the inner surface of the bladder.

Mucosal abnormalities should be documented as to their location, size, multiplicity, and appearance and ideally should be photographed. One crucial appearance that must be identified is the transitional cell carcinoma (TCC), the commonest form of bladder cancer (Figure 39.5). Smaller areas may be biopsied and the base coagulated. Larger areas may require formal resection.

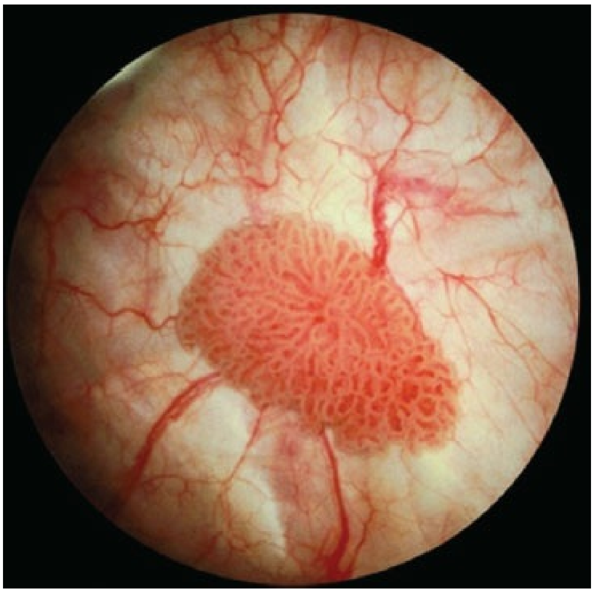

Figure 39.5 A small transitional cell cancer (TCC) of the bladder. The regular fronding of the lesion and normal-appearing nearby urothelium suggests it is probably a well-differentiated TCC.

Distension of the bladder may be used to help in the diagnosis of bladder pain syndrome (BPS). This is a symptom complex of bladder pain associated with at least one other urinary symptom in the absence of another diagnosis. Cystodistension allows the classification of BPS according to the International Society for the Study of Interstitial Cystitis classification, depending on the cystoscopic findings of glomerulations (Figure 39.6) or Hunner's ulcer, in addition to certain histological findings on biopsy.

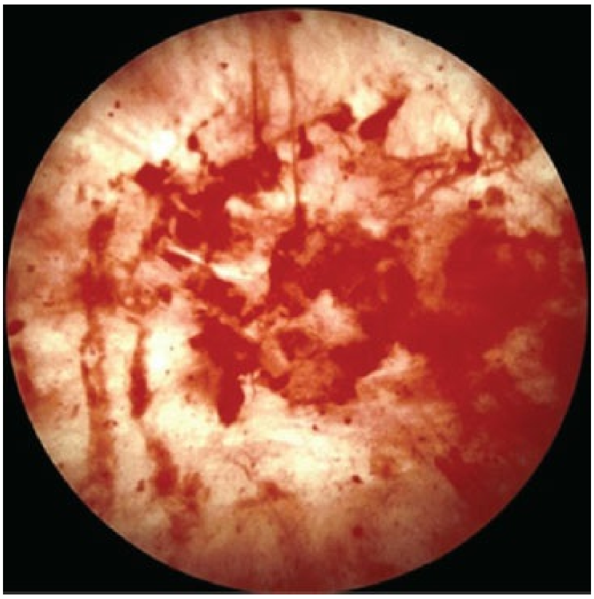

Figure 39.6 Bladder glomerulations after distension in a patient with bladder pain syndrome.

UPPER TRACT PROCEDURES

Once access to the bladder has been obtained, the upper tracts may be accessed via the ureteric orifices. Retrograde injection of contrast under radiographic screening allows definition of the upper tract anatomy, including filling defects caused by tumors or calculi. These abnormalities may be treated with laser lithotripsy. Self-retaining double-pigtail stents (Figure 39.7) can be inserted into the ureter. This may be done prophylactically to aid in identification of the ureter intraoperatively or to relieve obstruction or treat ureteric injury.

NEW DEVELOPMENTS IN ENDOSCOPY

The technological developments in the field of endoscopy have led to improved image quality with smaller, more maneuverable instruments. Refinements in optical technology have facilitated improvements in identification of abnormal tissue. Narrowband imaging refers to the use of light in the blue (415 nm) and green (540 nm) spectrum that are strongly absorbed by hemoglobin. This enhances the contrast between normal urothelium and hypervascular malignant tissue. The surface capillaries appear brown and the deeper veins cyan.

Fluorescence cystoscopy involves the administration of a photoactive porphyrin, e.g., hexaminolevulinate (HAL) or 5-aminolevulinic acid (ALA) 1 hour before cystoscopy. These porphyrins preferentially accumulate in malignant tissue and appear red under blue light (of wavelength 380–450 nm). There is some evidence that the use of fluorescence cystoscopy improves cancer detection rates and reduces recurrence [4].

The limitation on image quality of a normal cystoscope is the interface between the eyepiece and the camera. Digital endoscopes (Figure 39.8) rely on a charge-coupled device on the tip of the endoscope (“chip-on-the-tip”). The projection of the image onto the capacitor results in the accumulation of an electrical charge proportional to the light intensity at that location. These charges are processed into a high-quality image on the monitor. An LED illumination source is incorporated into the instrument, reducing the bulk and weight overall.

OPERATIVE TECHNIQUE (STEP BY STEP) [5]

Patient positioning varies according to the instrument used. The lithotomy position is used for rigid cystoscopy, while the supine position is standard for flexible cystoscopy. Skin cleaning and disinfection is required followed by administration of a lubricating local anesthetic gel.

Rigid Cystoscopy

Instrument Insertion

The comparative shortness of the female urethra allows investigation using a rigid endoscope.

Gently introduce the sheath without mucosal injury to avoid possible urethral strictures. Avoid using pressure or force.

Blind insertion with the closed instrument (sheath and obturator) is possible.

Inspect the urethra to rule out urethral tumors, diverticula, and fistulae.

Inspection of the Bladder

Start inspection with the 30° telescope, and use different telescope (i.e., 70°) to inspect all areas of the bladder (i.e., dome, bladder neck).

Start with inspection of the trigone and then systematically evaluate the base, lateral walls, and posterior wall.

Inspect the dome of the bladder by turning the cystoscope 180°. Sometimes manual pressure on the lower abdomen helps bring the dome into view.

Use irrigation fluid inflow and outflow as necessary.

Look for the following:

- Ureteral orifices (position and form)
- Tumors
- Trabecula
- Lesions of the mucosa
- Diverticula and fistulas
    - Stones and foreign bodies

Additional Investigations: Consider Additional Investigations as Indicated

- Bladder washing
- Vaginal and/or rectal palpation
- Vaginal inspection
- Stress test and Marshall–Marchetti test

Flexible Cystoscopy

The patient should empty the bladder prior to performing a flexible cystoscopy. Preparation and local anesthesia are discussed earlier.

Instrument Insertion

Use lubricating gel.

Slowly pass the cystoscope through the urethra with continuous-flow irrigation.

A systematic inspection of the bladder is mandatory as described earlier.

By deflecting the instrument more than 180°, it is possible to inspect the bladder neck in a retrograde fashion.

Consider repeating the cystoscopy if the vision is impaired due to debris, blood clots, or active bleeding.

Normal Findings

- Healthy bladder mucosa appears yellow to pink with small vascular branches.
- Ureteral orifices.
    - ◦ Located within the trigonal rim.
    - ◦ Slit-like or a flat indentation.
    - ◦ Refluxive orifices are commonly lateralized and/or horseshoe-like in shape.

Procedure Report

A report should be written at the end of every cystoscopy, if possible with schematic drawings or video documentation of pathologic findings.

***Practical Tips* [5]**

- Dynamic cystoscopy: Examination of the bladder under variable filling may also be helpful to inspect all areas.
- Chromocystoscopy: If ureteral orifices are not identifiable, use indigo-carmine-blue dye intravenously.
- ALA-induced fluorescence cystoscopy for the detection of lower urinary tract tumors.

***Common Complications* [5]**

- Pain and dysuria (occasionally)
- Bleeding or transient gross hematuria
- Traumatic lesion of the urethra (occasionally)
- Perforation of the bladder (very rarely), possible in pronounced bladder tumors and impaired vision or contracted bladder
- Traumatic urethral strictures due to mucosal lesions (uncommon)
- False passage especially in blind insertion of the instrument (Figures 39.9 and 39.10; see also Figures 39.11 through 39.13)

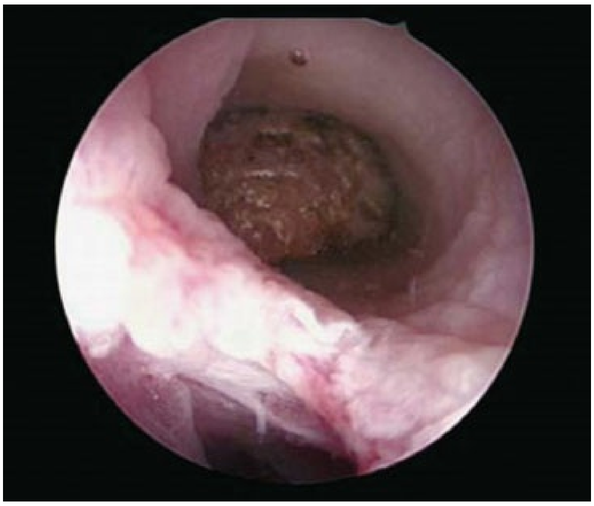

Figure 39.9 Urethral calculus with false passage. (With kind permission from Springer Science+Business Media: *Manual Endourology: Training for Residents*, 2005, Hohenfellner R and Stolzenburg J-U.)

***Limitations and Risks* [5]**

- Cystoscopy during untreated urinary tract infection (UTI) should be avoided because of a possible exacerbation of sepsis.
- Culture specimens are required to prove sterility of the urinary tract prior to endoscopy for patients with pyuria.
- Endoscopy should be performed after specific antibiotic therapy.
- Acute and heavy bleeding may lead to insufficient endoscopic evaluation.

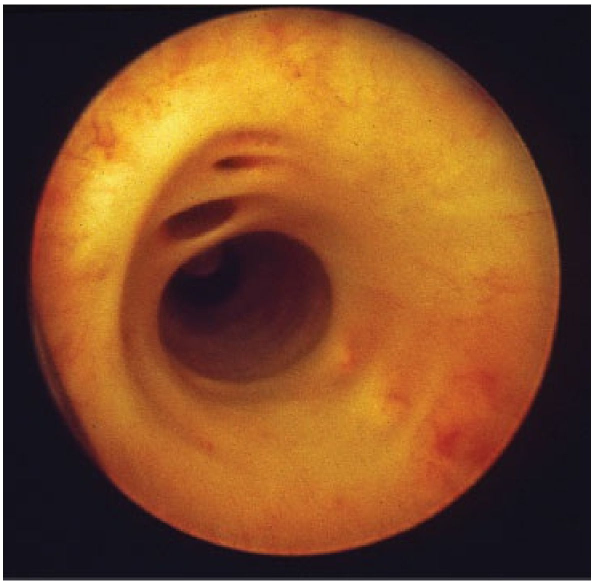

Figure 39.10 False passage urethra. (From Schönebeck J, *Digital Atlas of Cystoscopy*, Astra Tech, Molndal, Sweden, 2007, pp. 22–45.)

Contraindications [5]

- Acute urethritis, acute prostatitis, and acute epididymitis
- UTI
- Strong coagulopathy

NORMAL ENDOSCOPIC FINDINGS

Normally, the urethral mucosa is pink and smooth with a posterior longitudinal ridge, called the urethral crest (Figure 39.14). The ureterovesical junction (UVJ) is typically round or an inverted horseshoe shape and is completely coapted until the irrigating fluid opens the lumen. The UVJ normally closes briskly and has minimal mobility on Valsalva maneuver.

The bladder mucosa has a smooth surface with a pale pink to glistening white shade. The translucent mucosa affords easy visualization of the branched submucosal vasculature. The mucosa of the dome thickens and develops a granular texture as it gives way to the trigone. The trigone is triangular in shape, with the inferior apex directed toward the UVJ and the ureteral orifices forming the superior apices. As the cystoscope is advanced past the UVJ, the trigone is apparent at the bottom of the field.

The interureteric ridge is a visible elevation that forms the superior boundary of the trigone, running between the ureteral orifices. The intramural portion of the ureters can often be seen as they course from the lateral aspect of the bladder toward the trigone and ureteral orifices (Figure 39.15).

Although there is marked variation in the ureteral orifices, they are generally circular or slit-like openings at the apex of a small mound (Figure 39.16). With efflux of urine, the slit opens and the mound retracts in the direction of the intramural ureter.

The bladder is roughly spherical in shape when distended, but numerous folds of mucosa are evident in the empty or partially filled bladder. The uterus and cervix can be seen indenting the posterior wall of the bladder, which creates posterolateral pouches where the bladder drapes over the uterus into the paravaginal spaces. At times, visualization of the anterior bladder dome requires manual pressure on the lower abdomen.

URETHRAL FINDINGS

While congenital urethral anomalies are quite uncommon, urethral duplication has been reported, and typically the most anterior lumen drains the true bladder. Due to the blind ending and the possibility of urine deposition and entrapment in the false urethra, resection of the duplicate urethra may be required. Urethral stones and strictures are other frequent findings (Figure 39.17a and b).

Urodynamic Stress Incontinence

The urethral hypermobility typical of urodynamic stress incontinence causes the UVJ to open and descend in response to cough and Valsalva maneuver, and the patient may not be able to close the UVJ to the *hold* and *squeeze* commands. Urethroscopic findings typical of the patient with intrinsic sphincter deficiency include a rigid, immobile urethra with poor coaptation (Figure 39.18). In severe cases, the UVJ is unresponsive to commands and the lumen is visualized in its entirety from meatus to UVJ. Detrusor overactivity should be suspected if there is uncontrollable urethral opening during filling.

Female Urethral Diverticulum

UDs occur in 1%–3% of women and can be generally described as a periurethral cystic structure adjacent to the urethra. UDs are often diagnosed in the evaluation of nonspecific lower urinary tract symptoms including dysuria, pelvic pain, vaginal mass, dyspareunia, and recurrent UTIs. Their clinical presentations vary from completely asymptomatic, incidentally noted lesions on physical examination or radiographs to very debilitating, painful vaginal masses associated with incontinence, stones, and/or tumors. Anatomical variations between patients and in the location, size, and complexity of these lesions ensure that each case is unique [7]. The vast majority of UDs, however, are likely to be acquired and are diagnosed in adult females. In two large series of UD, there were no patients reported who were younger than 10 years of age arguing against a congenital etiology for these lesions [7–9].

The female urethra is a musculofascial tube approximately 3–4 cm in length, extending from the bladder neck to the external urethral meatus, suspended to the pelvic sidewall and pelvic the majority of the glands draining into the distal one-third of the urethra. Skene glands are the largest and most distal of these glands. These glands drain outside the urethral lumen, lateral to the urethral meatus. Most acquired female UDs are thought to originate from pathologic processes involving the periurethral glands [7]. In over 90% of UD cases, the ostium is located posterolaterally in the mid or distal urethra, which corresponds to the anatomic location of the periurethral glands [7,10,11]. UDs have been attributed historically to recurrent infection of the periurethral glands, with obstruction, suburethral abscess formation, and subsequent rupture of these infected glands into the urethral lumen.

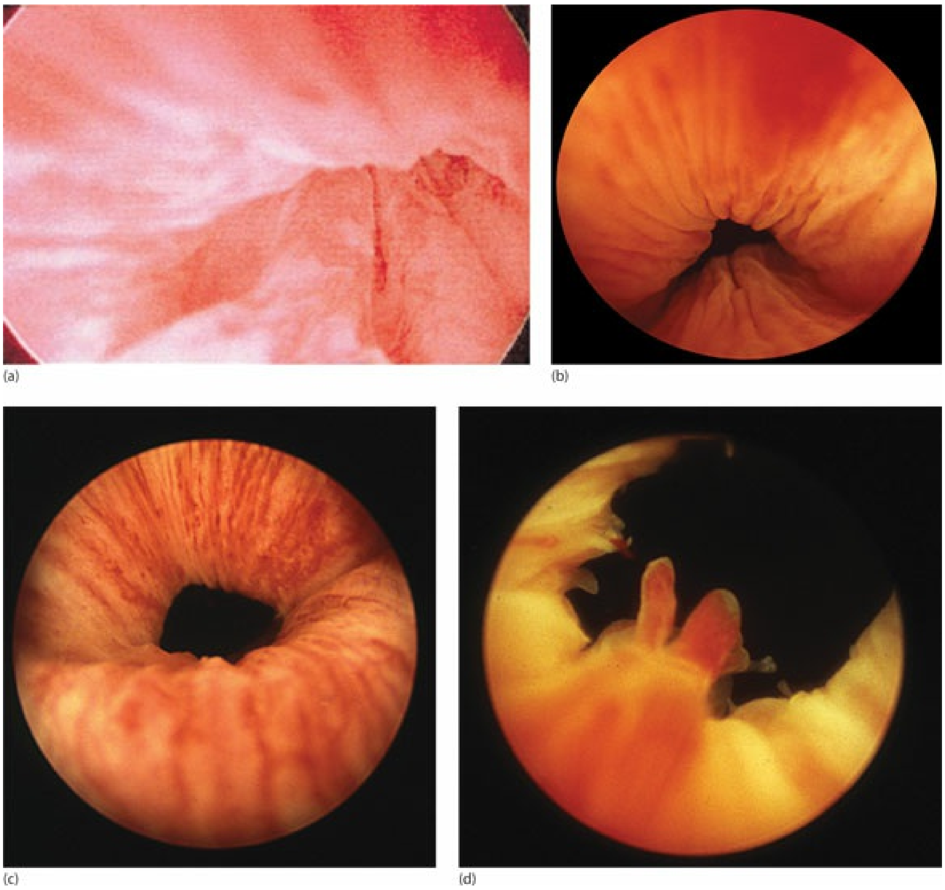

Figure 39.14 (a) Urethral lumen showing urethral crest and normal coaptation. (From Carr L and Cundiff GW, Endoscopy, in Cardozo L and Staskin D, eds., *Textbook of Female Urology and Urogynecology*, Informa, London, U.K., 2010. With permission.) (b) Normal female urethra. (c) Proximal urethral opening of normal female urethra. (d) Pseudopolyps close to the internal meatus—normal finding. (From Schönebeck J, *Digital Atlas of Cystoscopy*, Astra Tech, Molndal, Sweden, 2007, pp. 22–45.)

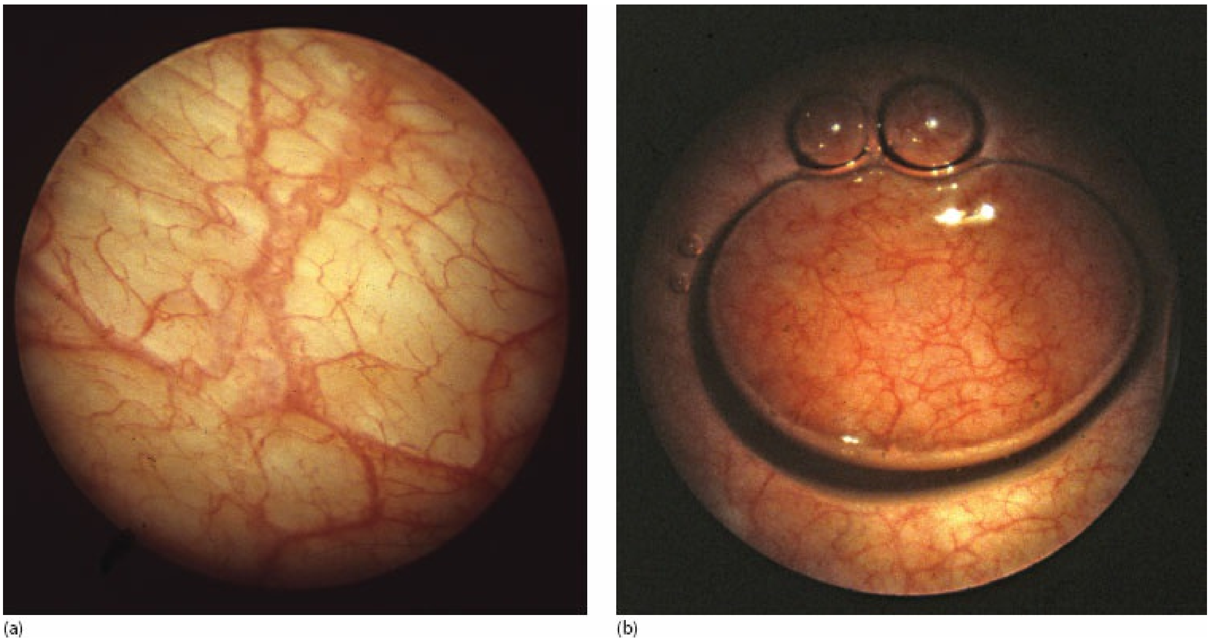

Figure 39.15 (a) Normal bladder. (b) Roof air bubble looking. (From Schönebeck J, *Digital Atlas of Cystoscopy*, Astra Tech, Molndal, Sweden, 2007, pp. 22–45.)

As conceptualized by Young and colleagues (1996), UDs represent a cavity dissecting within the confines of the fascia of the urethropelvic ligament [7]. This defect is often an isolated cyst-like appendage with a single discreet connection to the urethral lumen termed the neck, or ostium. However, complicated anatomic patterns may exist, and in certain cases the UD may extend partially ("saddlebag" UD) around the urethra, anterior to the urethra [12], or circumferentially around the entire urethra [7,13].

The urethroscopic diagnosis is most accurate when the bladder is filled, and a finger in the vagina occludes the bladder neck or proximal urethra. A steady flow of fluid into the urethra is maintained as the scope is withdrawn and the urethra massaged by the finger pressing upward from below (Figure 39.19).

BLADDER FINDINGS

Nonmalignant Bladder Lesions

Epithelial Metaplasia (Figure 39.20)

Epithelial metaplasia is focal areas of transformed urothelium with normal nuclear and cellular architecture surrounded by normal urothelium usually located on the trigone and composed of squamous (squamous metaplasia) or glandular (glandular metaplasia) cells. Squamous metaplasia often has a knobby appearance and is covered by white, flaky, easily disrupted material lying on the trigone. Glandular metaplasia appears as clumps of raised red areas that appear inflammatory and are often confused for cancer. Approximately 40% of women and 5% of men have squamous metaplasia of the bladder, which is usually related to infection, trauma, and surgery [14]. Spinal cord injury is associated with squamous metaplasia most likely from catheter trauma and UTIs [7].

Cystitis Cystica and Glandularis (Figures 39.21 and 39.22)

Cystitis cystica and/or glandularis is a common finding in normal bladders, usually associated with inflammation or chronic obstruction [15]. Cystitis glandularis can be associated with pelvic lipomatosis and may occupy the majority of the bladder. Cystitis glandularis may develop into or coexist with intestinal metaplasia, which are benign tumors. There have been a few case reports of cystitis cystica or glandularis transforming into adenocarcinoma, and therefore regular endoscopic evaluation of patients with these entities is recommended [7,16].

Eosinophilic Cystitis (Figure 39.23a through d)

Eosinophilic cystitis may appear as a red–brown patch cystoscopically, and the diagnosis can only be made by histological evaluation.

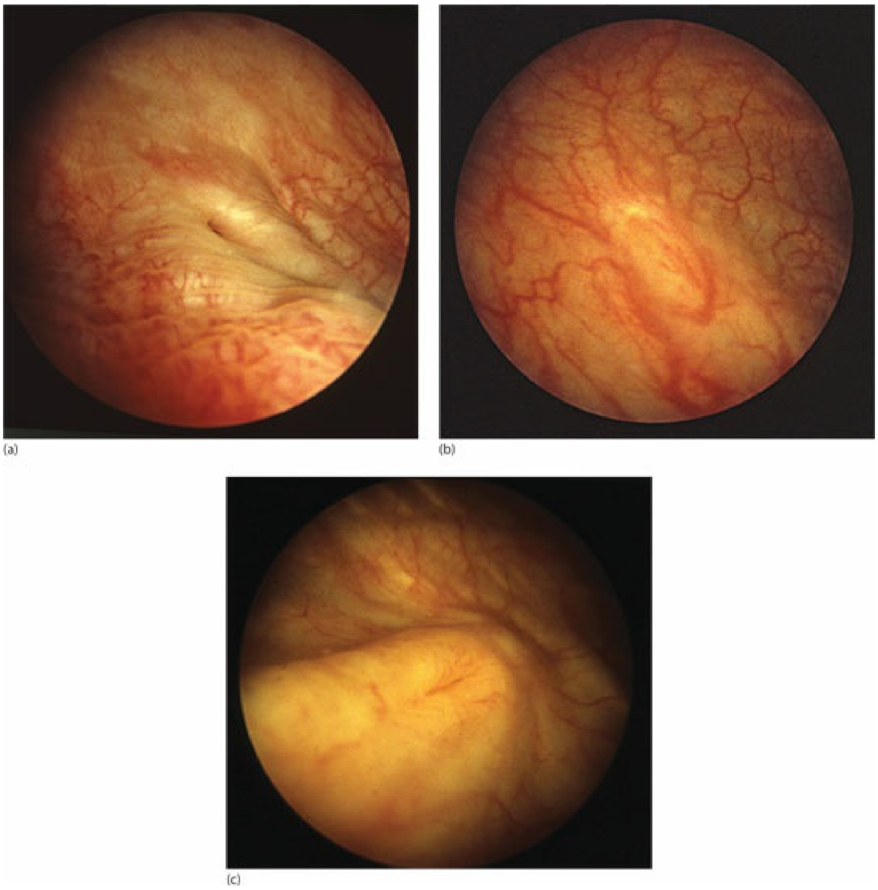

Figure 39.16 (a) Normal right ureteral orifice. (b) Ureteral orifice—difficult to discover. (c) Sleeping ureteral orifice. (From Schönebeck J, *Digital Atlas of Cystoscopy*, Astra Tech, Molndal, Sweden, 2007, pp. 22–45.)

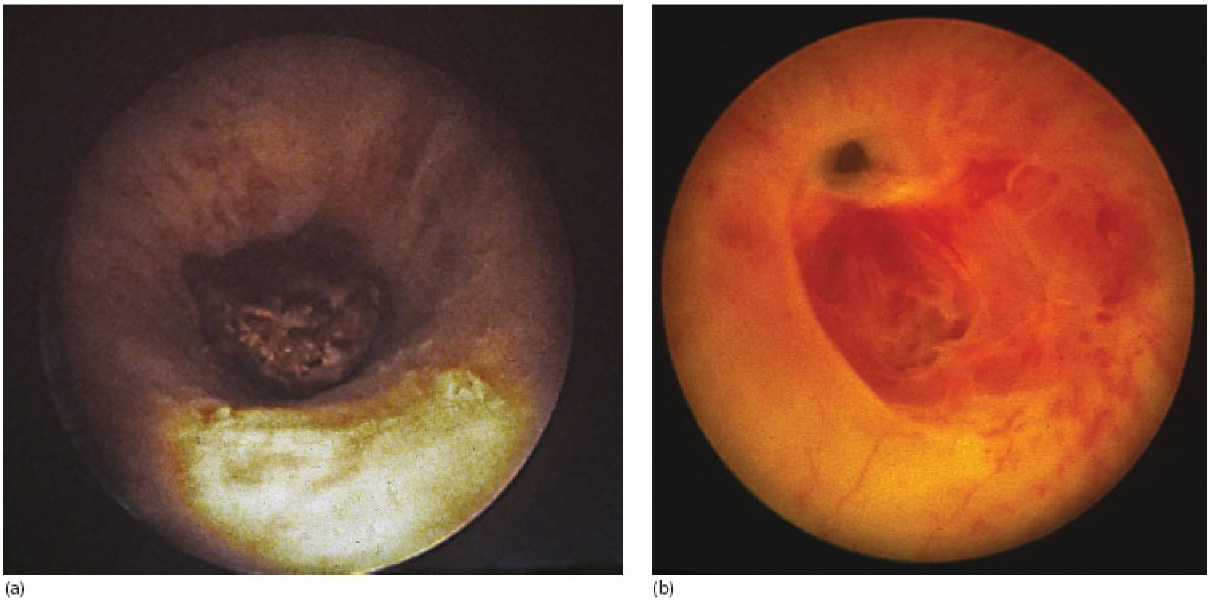

Figure 39.17 (a) Urethral stone stuck in the urethra. (b) Urethral stricture + false passage below. This false passage is the usual result of using force to catheterize patients with strictures and sometimes because of using the wrong technique in catheterizing a normal urethra! (From Schönebeck J, *Digital Atlas of Cystoscopy*, Astra Tech, Molndal, Sweden, 2007, pp. 22–45.)

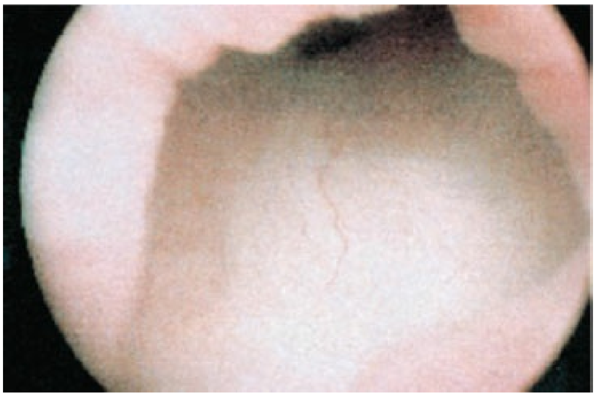

Figure 39.18 Intrinsic sphincteric deficiency. (From Carr L and Cundiff GW, Endoscopy, in Cardozo L and Staskin D, eds., *Textbook of Female Urology and Urogynecology*, Informa, London, U.K., 2010. With permission.)

Leukoplakia

Leukoplakia is similar to squamous metaplasia with the addition of keratin deposition that appears as a white flaky substance floating in the bladder. Leukoplakia occurs in other organs that are covered by squamous epithelium and is often premalignant. However, cytogenetic studies on bladder leukoplakia are consistent with a benign lesion, and no treatment is necessary [7].

Leiomyoma

Leiomyomas are the most common nonepithelial benign tumor of the bladder composed of benign smooth muscle. Leiomyomas appear as smooth indentations of the bladder and can be confused with a bladder tumor except for the normal urothelium overlying the tumor. These tumors occur most commonly in women of childbearing age and are histologically similar to leiomyomas of the uterus [7,17].

Bladder Trabeculations

Bladder trabeculations are most commonly associated with bladder outlet obstruction (Figure 39.24); nevertheless, this is a nonspecific finding. Grades of trabeculation have been proposed but none is universally accepted. As a general rule, more severe trabeculation has been associated with detrusor compromise. Histological analysis of trabeculations has demonstrated a mixture of smooth muscle bundles with an abundance of interfascicular collagen deposition.

Diverticula (Figure 39.25)

Diverticula are urothelial-lined pockets without smooth muscle backing that can either be congenital (i.e., Hutch diverticula located adjacent to a ureteral orifice) or acquired (commonly in the setting of outlet obstruction). They may have either a large or a narrow neck, and if poorly draining can be a source of recurrent infection.

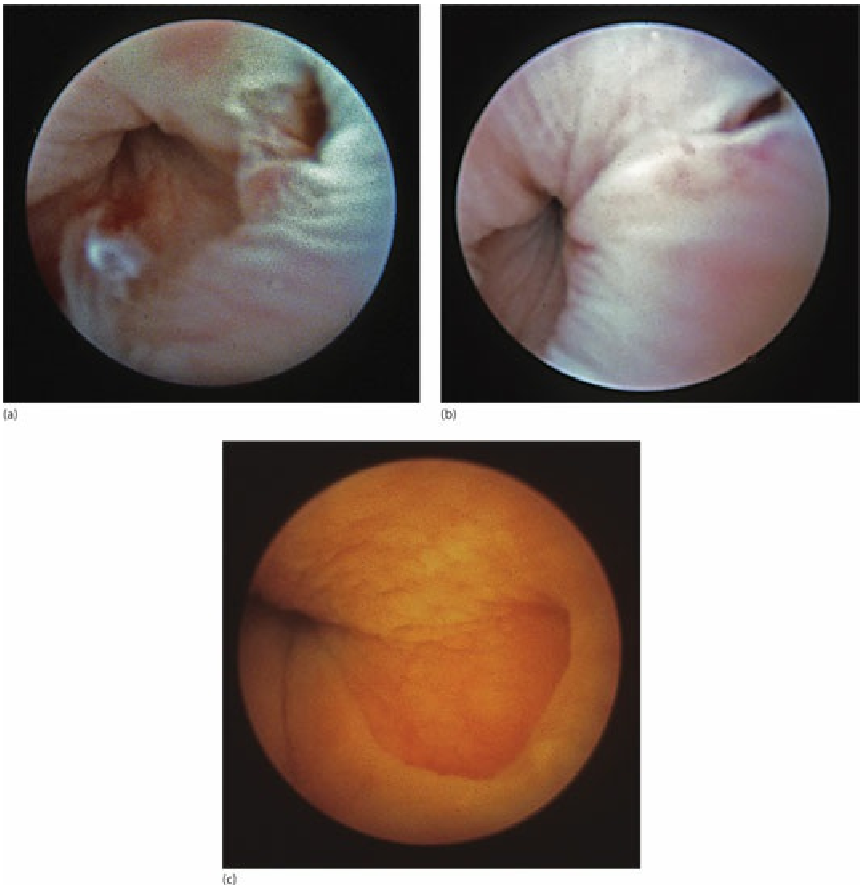

Figure 39.19 (a–c) Urethral diverticulum to the left. (From Schönebeck J, *Digital Atlas of Cystoscopy*, Astra Tech, Molndal, Sweden, 2007, pp. 22–45.)

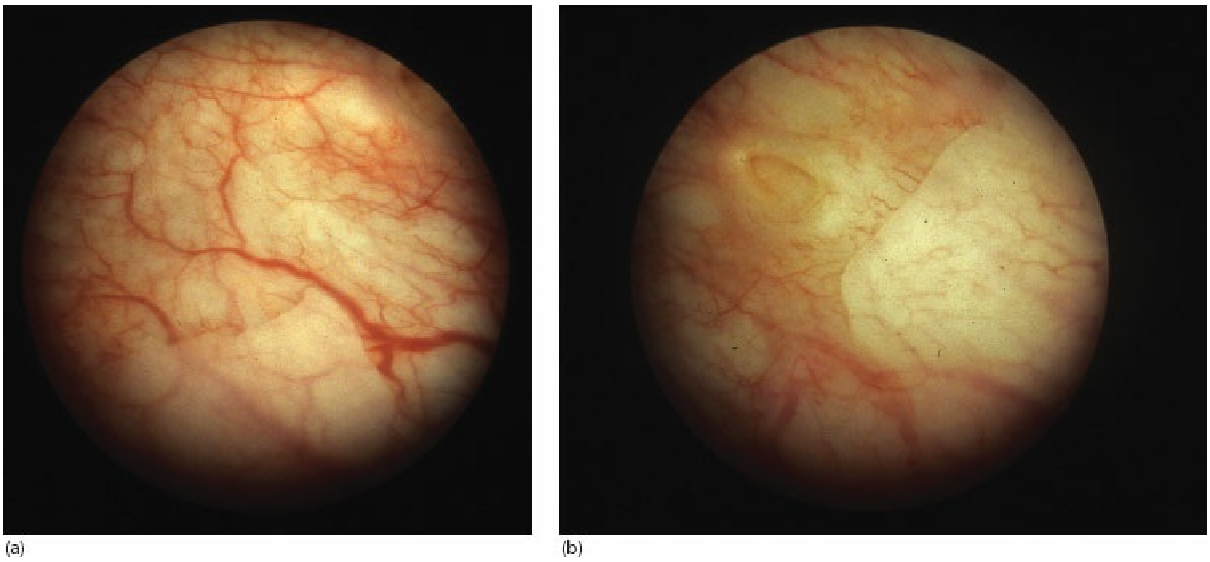

Figure 39.20 Normal bladder + epithelial metaplasia. (a) Bladder. (b) Trigone. (From Schönebeck J, *Digital Atlas of Cystoscopy*, Astra Tech, Molndal, Sweden, 2007, pp. 22–45.)

Foreign Bodies

Intravesical foreign bodies may present with hematuria or as urge incontinence due to mucosal irritation. Bladder calculi may result from urinary stasis or the presence of a foreign body, or an inflammatory exudate may coalesce and serve as a nidus for stone formation (Figures 39.26 and 39.27).

Stones have an extremely variable cystoscopic appearance in terms of color, size, and shape but generally have an irregular surface. Foreign bodies and stones are usually accompanied by varying degrees of general or localized inflammatory reaction.

Urinary Tract Fistulae

Fistula represents an extra-anatomic communication between two or more epithelial or mesothelial-lined body cavities or the skin surface. The potential exists for fistula formation between a portion of the urinary tract (i.e., kidney, ureters, bladder, and urethra) and virtually any other body cavity [7].

Diagnosis is made in three steps after a fistula is suspected. The first step is to confirm that watery drainage is urine; Pyridium may be used for this aim. The next step is to exclude urinary incontinence occurring from the urethra by filling the bladder and observing for loss from the urethra or vagina. Finally, the source of the fistula needs to be identified. This commences with a speculum inspection, which may reveal a fistula site to the vagina. The double-contrast test is also useful, although cystoscopy and the flat tire test are the best ways to visualize the fistula site in the bladder.

Vesicovaginal Fistulae

Vesicovaginal fistulae (VVF) are the most common acquired fistula of the urinary tract [18]. VVF are thought to result most commonly from an incidental unrecognized iatrogenic cystotomy located along the anterior vaginal wall at the level of the vaginal cuff [7,19].

Cystoscopy should be done in patients with a suspicion of VVF. Immature fistulae may look as an area of localized bullous edema without distinct ostia, while mature fistulae may have smooth margins with ostia of different sizes. Sometimes, it might be difficult to identify the exact fistula tract in a small VVF. In these cases, a guidewire or ureteral catheter can be placed through the cystoscope into the fistula tract. Visualization of the wire in the vagina confirms the exact location of the VVF on both the bladder and genital sides [7].

Cystourethroscopy can confirm the presence of the fistula and assess the size of the tract and the presence of collateral fistulae in addition to the location of the ureteral orifices in relation to the fistula. Small fistulae, usually less than 3–4 mm in diameter, may be amenable to simple fulguration, which can be performed at the time of cystoscopy [19]. This is crucially important in the situation of a prior history of pelvic malignancy; a biopsy of the fistula is often done to evaluate for the possibility of a recurrent malignancy [7]. Fistulae located near or at the ureteral orifice may require ureteral reimplantation. This type of requirement would usually mitigate against a completely transvaginal attempt at repair [7].

Bladder Pain Syndrome/Painful Bladder Syndrome/Interstitial Cystitis

Bladder pain syndrome/painful bladder syndrome/interstitial cystitis (BPS/PBS/IC) is defined with the triad of bladder pain, urinary frequency, and urgency. It is a distinct condition, and it is likely that the urgency experienced by these patients differs from that experienced by those with overactive bladder [20]. While BPS/PBS/IC remains largely a diagnosis made by symptom assessment, the inclusion of typical cystoscopic findings in the original National Institute of Arthritis, Diabetes, Digestive and Kidney Disease criteria [21] highlights the historical role of cystoscopy in the evaluation of patients with BPS/PBS/IC. More recent studies have downplayed the importance of cystoscopy for making the diagnosis [22].

Two different forms of IC/PBS have been described, and prognosis and treatment may vary depending upon the form detected. *Classical* disease is characterized by erythematous patches, termed Hunner's ulcers (or Hunner's patches), which occur in less than 10% of patients. Only cystoscopy can accurately determine if inflammatory disease is present, as only approximately 30% of these patients show abnormalities on urinalysis that would otherwise prompt a cystoscopic examination. *Nonclassical* disease is characterized by a normal examination on cystoscopy with typical symptoms and no evidence of any other pathology [23]. When Hunner's ulcers are seen on cystoscopy (Figure 39.28), biopsies should be taken from these lesions to exclude carcinoma in situ. No reports point to IC/PBS as a potential premalignant condition; however, it is important to rule out bladder cancer, especially the presence of carcinoma in situ in patients aged over 40 years with a smoking history. [23,24].

Hydrodistention under anesthesia is still considered by many urologists to be the "gold standard" to aid in the diagnosis of IC/PBS. Glomerulations, submucosal petechiae, are frequently seen after the irrigant pressure is released. The bladder capacity is measured at 80–100 cmH_2O (anesthetic bladder capacity) and is usually reduced in the IC/PBS patient (normal anesthetic bladder capacity, 800–1200 mL; in IC/PBS usually <800 mL). Distention is limited to short periods of time, typically 2–5 minutes at a pressure of 80–100 cmH_2O. Submucosal hemorrhage (glomerulations) is often seen after hydrodistention and typically resolves (Figure 39.29). In patients with Hunner's ulcer, a biopsy should be done to rule out the presence of malignancy and fulguration of ulcers should be performed. Hydrodistention should not be performed in these patients, to avoid profuse hemorrhage and possible bladder perforation. All biopsy sites, fulguration areas, and mucosal tear locations should be noted to avoid confusion of these lesions on future cystoscopic evaluation (Figure 39.30). Finally, instillation of 20–30 mL of a short-acting anesthetic agent, i.e., 1% lidocaine, may be helpful for patients undergoing hydrodistention to allow for faster recovery and decreased pain following the procedure [24].

Reduction of symptoms ranges from 30% to 56% 26. However, the overall mechanism of symptom relief after hydrodistention is still unknown 26. The procedure is considered safe; however, complications such as hematuria, bladder perforation, and bladder necrosis have been reported. Bladder perforation can usually be managed conservatively with catheter drainage. Vesical necrosis is a rare but serious complication of hydrodistention [24–26].

Malignant Bladder Lesions

Bladder cancer is the second most common cancer of the genitourinary tract. It accounts for 7% of new cancer cases in men and 2% of new cancer cases in women [27]. Bladder lesions of uncertain etiology must be investigated under anesthesia because of the common need for cold-cup biopsies and fulguration to determine their malignant potential. Urinary cytologies and other urinary markers are helpful in determining if malignant cells are present in bladder washings but none sensitive enough to prevent the need for tissue diagnosis.

The diagnosis and initial staging of bladder cancer is made by cystoscopy and transurethral resection (Figure 39.31). Superficial, low-grade tumors usually appear as single or multiple papillary lesions. Higher-grade lesions are larger and sessile. Carcinoma in situ (CIS) may appear as flat areas of erythema and mucosal irregularity. Use of fluorescent cystoscopy with blue light can enhance the ability to detect lesions by as much as 20% [28]. In this procedure, hematoporphyrin derivatives that accumulate preferentially in cancer cells are instilled into the bladder and fluorescence incited using a blue light. Cancer cells with accumulated porphyrin such as 5-aminolevulenic acid or HAL are detected as glowing red under the fluorescent light [27,29].

The World Health Organization recognizes a papilloma as a papillary tumor with a fine fibrovascular stalk supporting an epithelial layer of transitional cells with normal thickness and cytology. Papillomas are a rare benign condition usually occurring in younger patients [27].

Approximately 90% of all bladder cancers are TCC (Figure 39.32). These tumors most commonly appear as papillary, exophytic lesions; less commonly, they may be sessile or ulcerated. Whereas the former group is usually superficial in nature, sessile growths are often invasive. Carcinoma in situ typically has a flat, red, velvety appearance that may be multifocal [27].

Adenocarcinoma—Adenocarcinomas account for <2% of all bladder cancers. It may be preceded by cystitis and metaplasia. Primary adenocarcinomas often arise along the floor of the bladder, while adenocarcinomas arising from the urachus occur at the dome. Both tumor types are often localized at the time of diagnosis, but muscle invasion is usually present [27] (Figure 39.33).

Other malignant bladder lesions include squamous cell tumors and metastatic lesions. Squamous cell tumors are often associated with a history of chronic infection, bladder calculi, or chronic catheter use. It may also be associated with bilharzial infection (Figure 39.34). These tumors are often nodular and invasive at the time of diagnosis.

Melanoma (Figure 39.35), breast adenocarcinoma, and several other tumors have been noted to metastasize to the bladder, often resulting in repeated bouts of gross hematuria. Locally advanced malignancies, typically of the colon, can also directly invade the bladder wall and eventually disrupt the bladder mucosa, resulting in an abnormal cystoscopic appearance and hematuria.

Ureteral Anomalies

Ureteral anomalies are not uncommonly found in patients undergoing diagnostic cystoscopy. Duplicated systems can occur bilaterally or unilaterally, with two orifices from the same renal unit typically being adjacent to one another. The medial and caudal-most of the ureteral orifices normally serve the upper pole system. Vesicoureteral reflux is often present in the ureter serving the lower pole system (a finding confirmed on cystography) (Figure 39.36). In women, ectopic ureters may also be found to drain into the urethra and vaginal vestibule, though most of these abnormalities will be found in childhood secondary to ongoing incontinence (Figure 39.37).

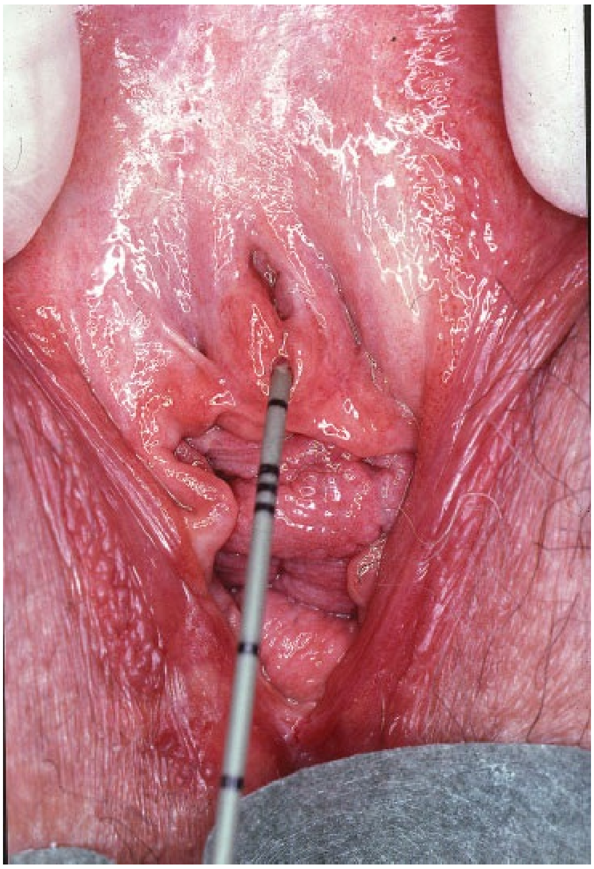

Figure 39.37 Ectopic ureteral orifice. (From Schönebeck J, *Digital Atlas of Cystoscopy*, Astra Tech, Molndal, Sweden, 2007, pp. 22–45.)

Asymptomatic, single system ureteroceles are also not uncommon in adults, with the typical appearance being a thin layer of urothelium covering a bulging orifice in a normal location. Often, a pinpoint opening is noted on the membrane, and due to urinary stasis, ureteral stone formation can occur proximal to this opening, particularly in children. Occasionally, ureteroceles will be ectopic in location, at times presenting as far distally as the mid and distal urethra (Figures 39.38 and 39.39).

Uncommon Findings in Cystoscopy

CONCLUSIONS

Endoscopy has revolutionized the treatment of urological disease and forms a cornerstone of modern practice. Technological developments have facilitated improved optics and smaller, more maneuverable instruments. This enables the treatment of increasingly complex pathology with less patient impact.

40 Urinalysis

F.M.E. Wagenlehner and Ganesh Thiagamoorthy

URINALYSIS AND URINE CULTURE

Urinalysis is an essential noninvasive investigation and has been described since the era of the ancient Egyptians [1]. Basic urinalysis, conducted by the patient's bedside or in the office setting, allows for rapid assessment of urine to screen for a number of concerning pathologies including infection, diabetes mellitus, dehydration, malignancy, nephropathy, and renal stones. More detailed analysis can then be carried out in a laboratory to confirm diagnoses.

Analysis of urine should be based on standardized procedures, taking into account the areas of sample collection, transportation, and the actual analysis. One of the most detailed guidelines in this respect is the European urinalysis guideline that is still valid today [2].

Urine Collection and Testing

Specimens requiring investigation should be collected in a sterile manner into a clean container. In patients without catheters, urogenital cleansing prior to sample collection usually reduces and at least does not worsen the risk of contamination [3,4]. A recent comparative study showed using “paper soap” or “cleansing wipes” reduced the risk of contamination more than cleaning solely with water, but this has not yet been incorporated into clinical practice because of concerns regarding the effect of the soap on the viability of bacteria and chemical analysis [5,6]. Women should be asked to wipe the area between the labia from front to back and clean specifically over the urethra. Urine should be voided with their legs spread and with two fingers parting their labia. After passing some of the urine into the toilet, the collection device should then be at least half filled with the “midstream urine” sample prior to emptying the rest of their bladder into the toilet [7].

In women with indwelling catheters, if the catheter has been in situ for less than 2 weeks, a sample can be aspirated with a sterile syringe or using a cannula adapter after disinfecting the needleless sampling port. For specimens that are intended to be sent for microbiology, special device kits are now available that allow the urine sample to be transferred directly from the indwelling catheter to a Vacutainer tube containing preservative [8]. In cases where a urinary tract infection is suspected and the catheter has been in situ for more than 2 weeks, the catheter should be replaced to improve resolution of symptoms, and urine culture should be obtained from the freshly placed catheter prior to the initiation of antimicrobial therapy [9].

The components of urine such as bilirubin, urobilinogen, urothelial cells, microbial cells, or crystals begin to deteriorate soon after production, while commensal bacteria tend to overgrow altering glucose concentration and pH and preventing accurate diagnosis of pathogens [10]. In view of this, urinalysis should ideally be performed on-site within 2 hours of specimen production [11]. When this is not possible, a sample should be refrigerated within an hour or a preservative used [12]. Appropriate selection of preservation method may be critical since some preservatives interfere with enzymatic measurements.

Physical Examination

Urine may be globally screened by a trained assessor as part of a preliminary evaluation.

Color may be an indicator of concentration with increased pallor indicating increased hydration. The presence of brown, purple, red, or orange may, respectively, be secondary to raised bilirubin, the presence of infection, blood secondary to infection or malignancy, or ingestion of certain foods or drugs such as beetroot or rifampicin [13].

Turbidity increases with the presence of sediment and may be an indicator of infection, urinary crystals, or contaminants such as creams or vaginal discharge.

Odor is another factor that must be considered. Concentrated urine has a typical smell while overt urinary tract infections tend to have a specific foul-smelling ammonium odor. Ingestion of some foods, for example, asparagus, can also has a result in a characteristic smell.

Chemistry Examinations

Most chemistry examinations are performed with dipstick test strips. Routine dipstick urinalysis screens for leukocytes, nitrites, red blood cells, protein, glucose, ketones, specific gravity, and pH. “Test pads,” the small squares on test strips, are impregnated with specific chemicals that, when in contact with urine, undergo a chemical reaction resulting in a color change. The severity of the color change is then compared to the color on the chart, usually on the container to read the results. To reduce variation between users, optical readers are available that provide printed results. Abnormal urine color must be noted from the physical examination as this may lead to misinterpretation of the test pad color changes giving incorrect results [10].

Leukocytes are detected on the basis of indoxyl esterase activity released from lysed neutrophil granulocytes or macrophages. The detection limit is approximately 20×10^6 WBC/L.

Nitrites are found secondary to the activity of the nitrate reductase that reduces nitrate to nitrite, which is present in a variety of Gram-negative uropathogenic bacteria such as *Escherichia coli*. Nitrate reductase is however not produced by Gram-positive bacteria such as *Enterococcus* spp. and *Staphylococcus* spp. A positive nitrite test also requires nitrate in the patient’s diet (vegetables) to be excreted into urine and then incubated with nitrate reductase producing bacteria for at least 4 hours. Lower exposure times, e.g., in the case of patients with storage lower urinary tract symptoms leading to increased daytime frequency, could lead to false-negative results.

Red blood cells, hemoglobin or myoglobin in urine, are chemically detected by the pseudoperoxidase activity shown by the heme moiety of hemoglobin or myoglobin. Red blood cells or hemoglobin in urine might stem from prerenal, renal, or postrenal disease or hemolysis. Myoglobin in urine can be detected in cases of muscle necrosis, rhabdomyolysis, or myositis. The sources cannot be differentiated by chemistry investigation. A positive dipstick reading of red blood cells merits further microscopic examination to confirm or refute the diagnosis of asymptomatic microscopic hematuria.

Proteins in urine are a mixture of high- and low-molecular-weight proteins from plasma, kidney proteins such as Tamm–Horsfall protein, and proteins from the urinary and genital tract. Mucoproteins and low-molecular-weight proteins are less sensitively detected and Bence–Jones proteins are not detected. The test strip method mainly detects albumin at a concentration limit of 20 mg/L. Albumin concentrations less than 20 mg/L, termed “low-grade albuminuria,” may be suspicious for early glomerular damage. In order to screen for proteinuria resembling kidney damage in spot urine samples, the protein/creatinine ratio test has been designed. In morning urine samples, this technique compares favorably with 24 hours urine protein excretion with a threshold of 0.94 g/g creatinine to detect urine protein excretion of 1 g and 2.84 g/g creatinine to detect urine protein excretion of 3 g in 24 hours collections [14].

Glucose is found in urine when the volume of glucose filtered out of the blood stream by the glomerulus is greater than that that can be reabsorbed by the proximal renal tubule. The differentials for this include diabetes mellitus, pregnancy, Cushing’s syndrome, hepatobiliary, and pancreatic diseases.

Ketone bodies measured in the urine are acetoacetate and acetone and, to a lesser extent, β-hydroxybutyrate. Ketone bodies are elevated during diabetic hyperglycemia and ketosis, as well as after (overnight) fasting and inflammatory diseases of the bowel.

Specific gravity is measured using a chemical test and assesses the osmolality of urine compared to that of water. Specific gravity usually ranges between 1.003 and 1.035. A specific gravity close to 1.002 would be considered very dilute, while a level of 1.035 would be very concentrated.

Urinary pH is usually between 5.5 and 6.5 but can vary between 5 and 9, depending on diet and exercise. Urine pH is measured for diagnosis of acid–base disturbances. For example, in renal tubular acidosis or uric acid stone disease, urinary pH is constantly elevated or decreased, respectively. Bacteria metabolizing urea to ammonia, such as *Proteus mirabilis*, increase urine pH to 8.0 or higher.

Pregnancy tests are conducted on urine sample using specific test kits to measure human chorionic gonadotropin (hCG) secreted by the developing placenta. hCG is found at concentrations up to 10,000 IU/L in urine in early pregnancy and can be detected sensitively in urine in early pregnancy. The best urine sample for evaluation of hCG is the concentrated morning urine. A normally developing pregnancy will produce an hCG level of 25 IU/L 3–4 days after implantation. Most urinary pregnancy tests are sensitive to concentrations of 25 IU/L and therefore detect pregnancy up to 4 days prior to a missed period [15].

Particle Analysis

Particle analysis is the detailed assessment of urinary components either manually, mostly under a microscope, or via automated microscopy and flow cytometry [6]. It can be performed in unprocessed urine or using staining and can be performed in both centrifuged and noncentrifuged samples. There is a consensus that for most cases of routine examination, centrifugation is not necessary.

Some of the commonest particles found are white and red blood cells.

Leukocytes

Granulocytes are the most frequent leukocytes detected in the urine and are mainly observed as a response to urinary tract infection. In asymptomatic bacteriuria, granulocytes may also be seen, and their presence does not preclude the diagnosis of asymptomatic bacteriuria.

Macrophages also commonly appear in the urine of patients with urinary tract infection. In glomerulonephritis, interstitial nephritis, or interstitial cystitis, the major immune cellular components seen are granulocytes.

Lymphocytes in urine are more associated with viral diseases and renal transplant rejection.

Red Blood Cells

Red blood cells in urine, and their morphology, may reflect the origin of bleeding. Dysmorphic red blood cells are of an abnormal size or shape (erythrocytes usually have a diameter of 4–7 mm) and suggest renal disease, whereas normal morphology usually suggests the source to be the lower urinary tract. Accordingly, they can determine whether the subsequent diagnostic workup should be urological or nephrological.

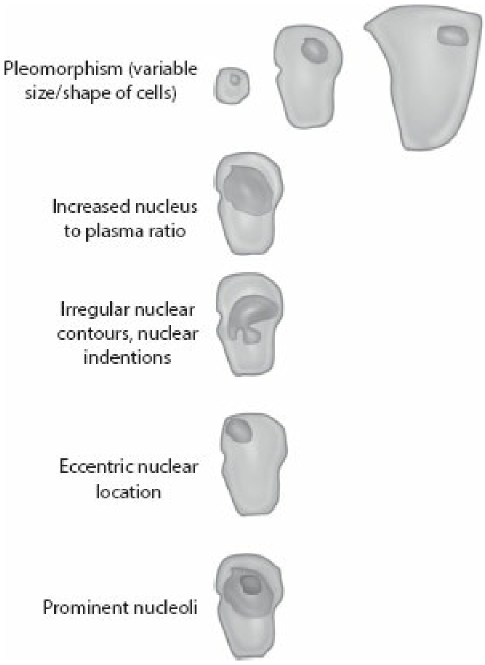
Other Cells

Urothelial cells derive from the multilayered epithelium lining the urinary tract.

The appearance of squamous epithelial cells is a marker of contamination by poor collection technique. During pregnancy, epithelial cells in urine are increased regardless of quality of the collection technique.

Casts

Casts are particles formed in the distal tubules and collecting ducts and usually reflect the presence of renal disease. Within casts, plasma proteins, lipids, different types of cells, microorganisms, pigments, or crystals may be found.



Pleomorphism (variable size/shape of cells)
Increased nucleus to plasma ratio
Irregular nuclear contours, nuclear indentions
Eccentric nuclear location
Prominent nucleoli

Figure 40.1 Schematic drawing of general cytomorphological features suggesting malignant cells.

Bacteria

Bacteria are detected at concentrations above 10^5 colony-forming units/mL (cfu) and centrifugation does not increase diagnostic accuracy. Applying Gram staining to centrifuged urine can increase diagnostic accuracy, but this is dependent on bacterial density.

Urine Cytology

Urine cytology is an important form of particle analysis used to investigate patients who are at risk or under surveillance for urothelial carcinoma. Several classification systems for urine cytology have evolved over the years [16–20]. General cytomorphological features suggesting malignant cells include nuclear hyperchromasia, irregular nuclear contours, abnormal chromatin texture, prominent nucleoli, eccentric nuclear location, nuclear indentations, increased nucleus-to-cytoplasm ratios, and high cellularity (Figure 40.1).

Urine cytology has a high sensitivity and specificity for high-grade urothelial lesions, such as carcinoma in situ, but low sensitivity and low negative predictive value in patients with low-grade urothelial tumors. Additional methods include fluorescence in situ hybridization techniques and various molecular approaches that are under evaluation currently.

Urine Culture

The aims of urine culture are to identify pathogens of urinary tract infection and estimate the concentration of bacteria and susceptibility to antimicrobials. The most commonly implicated bacteria in urinary tract infections are enterobacteria, such as *E. coli, Klebsiella* spp., *Enterobacter* spp., *Proteus* spp., non-fermenters such as *Pseudomonas* spp., and Gram-positive bacteria such as enterococci and staphylococci (*Staphylococcus saprophyticus*).

Dipslide testing does not reliably detect pathogen inocula of 10^4 cfu/mL or lower. However, in acute uncomplicated cystitis, colony concentrations of midstream urine samples are at concentrations of $\leq 10^3$ cfu/mL, so must be detected by additional tests such as plating on agar mediums, such as cystine lactose electrolyte deficient agar plates. A Gram-negative selective agar, such as MacConkey agar, can also be used.

Despite the presence of large numbers of bacteria, false-negative results may be obtained if patients have already commenced on antimicrobials. Special tests, such as the *Bacillus subtilis* test, help to detect antimicrobials in these circumstances.

Susceptibility testing allows the clinician to choose the correct antibiotic for treatment of urinary tract infections. There are several standardized methods available, such as disc diffusion, dilution, and epsilometer testing [21]. Susceptibility testing is performed according to international standards (Clinical and Laboratory Standards Institute or European Committee on Antimicrobial Susceptibility Testing). Susceptibility testing using automated systems has also been available for several years in most microbiological laboratories.

Fastidious organisms are prevalent in 13.7%–27.0% of patients with chronic lower urinary tract symptoms [22,23]. Three commonest fastidious organisms involved in chronic urinary tract infections are *Ureaplasma urealyticum*, *Mycoplasma hominis*, and *Chlamydia*. These organisms are more difficult to culture as they have complex nutritional requirements. To assess for fastidious organisms, laboratories must carry out either polymerase chain reaction testing or utilize culture mediums that enrich for a wider range of species and culture this for a longer than the usual duration of 7 days [23,24]. Due to the cost and time implications, most laboratories do not routinely screen for fastidious organisms. A single 3-month empirical course of a low-dose quinolone or tetracycline antibiotics can effectively treat 82% of fastidious organisms and a second 3-month course can treat 96% [25]. In view of the prevalence of these organisms in patients with chronic refractory lower urinary tract symptoms, it is important that fastidious organisms are considered and appropriate investigations conducted or empirical treatment initiated.

Novel Techniques

New “point-of-care” microbiology assessments are being developed that might enable susceptibility analyses of urine samples within 4–6 hours. This technology could avoid empirical broad-spectrum antibiotic usage and allow a more targeted approach.

CONCLUSION

In summary, urine dipstick with or without urine microscopy and culture is an important baseline test into the well-being of a woman. Although most commonly used to confirm the presence of infection, it has the ability to assess multiple other important diseases or concerns.

Conservative and Minimally Invasive Therapies

41 The Role of the Continence Nurse

Angie Rantell

The role of the continence nurse (CN) is multifaceted and ever expanding. It has developed rapidly in the United Kingdom since the 1980s, and now most clinical commissioning groups (organizations set up to organize the delivery of health services in England) offer a continence service that is run by specialist nurses.

These specialists provide a comprehensive assessment of all patients with continence needs and, if applicable, will implement conservative and pharmacological management plans. CNs have a role in education and health promotion for patients and other health-care professionals (HCPs). They also act as counselors when dealing with the negative psychosexual, emotional, and social impact that incontinence can have on an individual's quality of life. Generally, CNs are the first HCPs that patients are referred to, following disclosure of an incontinence problem, which places them in a prime position to undertake further research into the field especially with regard to etiology, epidemiology, quality of life improvements, and assessment of successful management.

A survey in the United Kingdom [1] reported the benefits of better continence care including the following:

- Reduces admissions to permanent care settings—nursing homes, secondary care, and homes for disabled adults and children.
- Reduces costly emergency admissions to secondary care with urinary tract infections, pressure ulcers, and catheter-related infections.
- Reduces prolonged use of costly incontinence products through low-cost interventions such as physiotherapy and medication.
- Better continence care contributes to independent living and improved quality of life.

According to the National Health Service (NHS) Modernisation Agency, continence care is the total care package tailored to meet individual needs of patients with bladder and bowel problems. This chapter will further discuss the varied roles that CNs perform to be able to provide a continence care package for all patients.

RANGE OF NURSING ROLES WITHIN CONTINENCE CARE

When continence services were first introduced, they would often provide care for all patient groups. However, now with the expanding needs of these services, specialized areas have emerged. Table 41.1 shows the different nursing specialities within continence care. These subspecialities are essential to offer expert care to all patients in primary, secondary, and tertiary care.

There is also a distinct range of nursing roles within the field including nurse consultants, clinical nurse specialists, continence advisors, staff nurses, and health support workers. Some may work alone or as part of a larger multidisciplinary team.

Austin [2] undertook a postal survey of continence advisors working in one health region to assess the differences in their roles and, in total, 41 responded. All of them had clinical contact with patients. Of the continence advisors surveyed, 50% had been involved in research relating to their specialty. A high proportion of respondents were involved in the education of nurses, medical staffs, and other HCPs. Most were involved in producing standards, protocols, and guidelines and all had an organizational wide remit in an advisory role. Many were responsible for auditing the practice of others and 65% managed other staff within their team. For providing advice or approval regarding purchasing and supply of specialist products, 90% were responsible and half of them held their own budget. This paper demonstrates the many different roles that a CN must perform to provide a full service.

ASSESSMENT

Incontinence is a symptom of an underlying disorder. A complete continence assessment will help to identify possible causes by building a complete picture of bladder and bowel dysfunction. A thorough initial assessment is important to determine incontinence type and rule out infections or other causes [3]. According to Lloyd [4], the procedure of taking a patient history allows the patient to present their account of the problems and provides essential information to the practitioner. There are many different models of assessment that can be utilized for this; however, many units will have developed their own proforma to standardize assessment in their specialist area. These may not only be used for specialist assessment but can also be used to standardize continence assessment for general nurses and to help ensure appropriate referral for patients with continence issues. Figure 41.1 demonstrates a continence assessment proforma that is designed for general nurses to help identify and assess hospital in-patients with bladder or bowel dysfunction. The Royal College of Nursing (RCN) has also published a framework for the assessment of continence in care homes that provides key questions and suggestions where residents of a care home may have continence problems Royal College of Nursing, Continence care in care homes – A framework to gather and share key information, London, UK, RCN, 2007.

The quality of assessment will be greatly enhanced by the participation of the patient and carers to the assessment process ensuring that the patient's wishes are foremost and, wherever possible, her own words are used to reflect her needs [5]. For this to be put into practice, the CN needs to have excellent interpersonal skills to build a trusting and open relationship with the patients and carers, encouraging them to voice their feelings and views about their problems.

Figure 41.1 Continent assessment form.

There are many components that are needed to perform a full continence assessment, and these will differ depending on local/national policies, as well as the CN's level of experience/expertise and the specialization within the field. It will also depend on the wishes of the patients and their desire for treatment or management. In 2000, the Department of Health [6] published a paper on good practice in continence services. This suggested key components that should be performed during a routine continence assessment. These are listed in Table 41.2.

SPECIALIST INVESTIGATION

CNs need a full understanding of different investigations that can be performed to assess and diagnose the causes of a patient's incontinence. They will not only be responsible for referring patients for further testing but also for performing investigations on their patients. Such investigations may be simple procedures such as urinalysis or more complex studies such as uroflowmetry, bladder scanning, subtracted cystometry, video cystourethrography (VCU), ambulatory urodynamics, flexible cystoscopy, anorectal physiology and manometry, and barium meals/enemas. To be able to perform these investigations, CNs may need specialist training in the procedures and may also need to gain further qualifications (e.g., good urodynamic practice). For CNs performing VCUs and barium studies, they may also have to be assessed and work within regulations for ionizing radiation (medical exposure), which can involve a theoretical exam and clinical assessment. This should be addressed in line with local policies.

Table 41.2 Key Components of a Continence Assessment

- Review of symptoms and their effect on quality of life.
- Assessment of the patient’s desire for treatment and possible alternative management.
- Examination of the patient’s abdomen for palpable mass or retention of urine.
- Examination of the perineum to identify prolapse and excoriation and assess pelvic floor contraction.
- Rectal examination to exclude fecal impaction.
- Urinalysis to exclude urinary tract infection.
- Assessment of manual dexterity.
- Assessment of the patient’s environment—access to the toilet.
- Use of a bladder diary/frequency/volume chart/bladder scan.
- Identification of conditions that may exacerbate the patient’s incontinence—medication, coughs, and drinking habits.

Source: Department of Health, Good practice in continence services, DH, London, U.K., 2000.

There are many different levels to which CNs will perform investigations depending on their level of expertise and training. Some may be technically experienced but unable to interpret the results of the tests in relation to the patient’s symptoms; however, the more experienced nurses will be able to assess, analyze, and interpret the results of any investigation that they perform.

Part of these investigations may involve internal examinations (vaginal and rectal). Prior to performing these examinations, it is essential to consider what information will be gained, whether it is a screening or diagnostic procedure and whether it is necessary at the time [7]. Informed consent should be gained verbally from all patients prior to investigation and, in some cases, written consent may also be necessary. Consideration should also be taken to ensure that the environment in which the assessment or investigation takes place is appropriate to meet the needs of the patient and the requirements of the investigation. Table 41.3 lists some of these environmental considerations.

Table 41.3 Environmental Considerations for the Assessment

The environment that the assessment takes place in should be
- Accessible
- Maintains privacy and dignity
- Hand washing facilities
- Male/female toilets
- Clean
- Warm
- Good lighting
- Appropriately equipped
- Free from distraction
- Safe for the patient and the nurse

Sensitive to religious and cultural needs

DECISION-MAKING

Hamilton and Martin [9] state that “Information acquisition is not the end point for practitioners. Having the information is one thing but deciding on the implications of it and on what to do with the information is the essence of professionalism in nursing.” Specialist practice is the exercising of higher levels of judgment, discretion, and decision-making in clinical care [10].

Management of incontinence should take into consideration patients’ individual needs and preferences, and patients should have the opportunity to make informed choices about their care and treatment [11]. It has been shown that patient empowerment is the most dynamic, effective, and efficient approach to care [12]. This places choices and decisions into the hands of those with incontinence.

Working as autonomic practitioners, CNs play a large role in decision-making. This includes the analysis and interpretation of investigations along with clinical observations and the information gained from taking patients history to make a clinical diagnosis and appropriate management plan. Once a diagnosis has been made, CNs have a responsibility to fully inform patients and carers what type of incontinence they have and the treatment options available. With this knowledge, a management plan can be set based on the CN's recommendations and patients' choice and in line with local policies.

Kurtz et al. [13] developed the Calgary–Cambridge Observation Guide (CCOG) model of consultation. It facilitates continued learning and refining of consultation skills for nurses through five stages as described in Table 41.4.

Along with diagnosing, outlining, and implementing management strategies, CNs must also be able to make clinical decisions as to when patients need to be referred on for further investigation or more specialist care. This may be to a specialist within the field, e.g., urogynecologist/urologist or colorectal team for surgery or to a different specialty following abnormal findings during assessment or exacerbation of a preexisting comorbidity that may be impacting upon their incontinence (e.g., heart failure or diabetes).

Table 41.4 Five Stages of Calgary–Cambridge Observation Guide

1. *Explanation and planning*—giving patients information, checking that it is correct and that you both agree that the history has been taken.
2. *Aiding accurate recall and understanding*—making information easier for the patient using reflection.
3. *Achieving a shared understanding*—incorporating the patients perspective to encourage an interaction rather than a one way transmission.
4. *Planning through shared decision making*—working with patients to assist understanding and involving patients in the decision-making process.
5. *Closing the consultation*—explaining, checking, and offering a plan acceptable to the patients needs and expectations.

Source: Kurtz S et al., *Acad Med*, 78, 802, 2003.

CONSERVATIVE MANAGEMENT

The most recently published guidelines on urinary incontinence from the *5th International Consultation on Incontinence* (2013) [14] and NICE CG171 [11] recommend initial lifestyle interventions followed by conservative management, which is usually pelvic floor physiotherapy for stress urinary incontinence and behavioral therapy, such as bladder retraining for overactive bladder (OAB). CNs play a major role in the implementation of these conservative management strategies through patient education and health promotion. According to Kelly et al. [15], CNs can identify causes, create treatment plans, and empower patients with incontinence and be involved in all aspects of their care. It has also been demonstrated that this service can be provided by CNs in a more cost-effective manner [16].

PHARMACOLOGICAL MANAGEMENT

Many CNs are working not only as advanced practitioners but also as autonomic practitioners and this has been helped with the advances in nurse prescribing. Whether CNs are working as independent or supplementary prescribers or within the bounds of patient group directives, it means that patients can also access pharmacological treatment if appropriate for their type of incontinence through the nurse-led service. Long-term monitoring and adjustments of these medications can also be performed through the nurse-led service thus reducing waiting lists for medical teams with the specialty. Also, some general practitioners may not have an in-depth knowledge of the different medications available, their modes of action, and how to monitor progress so specialist nurses can advise other general health-care providers in these matters.

PADS, CATHETERS, AND ANTI-INCONTINENCE DEVICES

Management of incontinence with the use of pads, catheter, or nonsurgical devices is appropriate for some patients. CNs are responsible for assessing the need for these and providing the necessary education for patients using them as a coping strategy in either the short term while awaiting further treatment or surgery or the long term for people with intractable incontinence. Some CNs who hold a budget may also have a role in the negotiation of contracts and provision of these products in line with local policy and needs assessment.

For patients using long-term catheterization (intermittent, urethral, or suprapubic), CNs should focus on educating patients/carers in infection control procedures and should perform a periodic reassessment to confirm the continued need for catheterization. Further information and guidelines are available from the RCN Catheter Care—a guide for nurses [17]. There has also been a website developed by the International Consultation on Incontinence to guide health professionals and patients on available containment products and the evidence behind their use. This can be accessed at www.continenceproductadvisor.org/.

MINOR SURGERY

One of the expanding roles of all specialist nurses has been in the performance of minor surgery. For CNs, this has included performing procedures such as flexible cystoscopies, insertion of suprapubic catheters, intradetrusor injections of botulinum toxin A, and colonoscopies under local anesthetic or mild sedation. To perform this role, CNs must have an advanced level of understanding of anatomy and physiology and be experienced and proficient clinical decision makers. A formal assessment pathway to ensure competency must be performed by an appropriate medical professional to ensure safe practice in line with regulatory bodies and individual trust protocols. With the advent of more surgical devices for incontinence that can be inserted under local anesthetic, this role may soon expand further.

COUNSELING SKILLS

People with incontinence often adopt coping behaviors to manage or reduce their symptoms (e.g., toilet mapping, dietary, and fluid restrictions). Coping strategies and symptoms of incontinence can have a profound effect on health-related quality of life, negatively impacting on even simple daily activities. People with incontinence may be reluctant to travel, visit friends and family, or pursue leisure activities for fear of embarrassment [18]. The psychological burden of incontinence can be severe, leading to depression and low self-esteem. Furthermore, some coping strategies are not only inconvenient but can also have serious medical sequelae [19].

Despite the debilitating effects of OAB, almost half of symptomatic people do not seek health-care advice, often because of shame and embarrassment [20].

Barriers to treatment seeking can include

- Embarrassment
- Lack of knowledge about the condition and management
- Belief that incontinence is a normal part of aging and not a medical condition
- Availability of products to contain incontinence
- Fear of physical examinations, invasive testing, and surgery
- Low expectations regarding treatment

To overcome these barriers, CNs need to aim to improve patient education to allay fears and misconceptions and promote awareness of symptoms and treatments.

HEALTH PROMOTION

CNs are often in the prime position to provide information to patients and relatives/carers on health promotion. This may be in the form of diet and lifestyle advice (e.g., fluid and caffeine reduction), weight loss or smoking cessation, and information on what are considered to be normal bladder and bowel habits.

Continence is now becoming a more public subject. In the past, it has been considered a taboo that should not be discussed in public; however, with large numbers of women experiencing continence problems, it is the ideal time to improve awareness and knowledge. This has been achieved in many ways. For example, the International Continence Society has run a World Continence Week every year to actively promote continence awareness and the services and treatments offered and address any myths associated with the subject.

In modern times, with more and more women seeking information and help from the Internet, it provides HCPs and charitable foundations with the opportunity to provide accurate health promotion information to a wider audience.

Many of the charities associated with this field (e.g., the Bladder and Bowel Foundation and the

Overactive Bladder and Interstitial Cystitis Group) also provide user support groups where women with similar problems can share their experiences and help each other through the difficulties associated with the diagnosis and management of chronic conditions.

EDUCATION

Education forms a large part of the CNs' role. They educate not only patients but also carers, relatives, colleagues, and other HCPs. Patient education can often be the most difficult. Often, it has to be tailored to individual patient needs taking into account their degree of understanding, cultural sensitivities, and the level of knowledge that they need or wish to have. However, there is a growing trend toward "the expert patient" [21] where, it is possible that the patient with a chronic condition will actually know at least the same if not more on disease management than the HCP giving the care.

CNs are considered to have an in-depth knowledge and experience in the field and therefore act as clinical advisors and educators to other HCPs to raise awareness of continence issues in different medical settings. Table 41.5 sets out the responsibilities of the CNs with regard to education as suggested by the RCN [22].

MAXIMIZING COMPLIANCE

Compliance is a medical term that is used to indicate a patient's correct following of medical advice. It applies to medication, the use of surgical appliances, or attending courses of therapy. It is also known as adherence, persistence, or concordance. There are several reasons as to why we should promote compliance to therapy as shown in Table 41.6.

Poor adherence to medication represents a major challenge in the management of urinary incontinence [23]. There are many factors that can influence compliance with therapy and these are enumerated in Table 41.7. Before starting therapy, it is important to ensure that patients are counseled regarding the role of therapy, medication, or surgery. This should include information on the side effects, the estimated length of treatment, other therapies available, how medication will improve their symptoms and how long it may take to be able to notice these differences, postoperative recovery and risks, and benefits of each intervention. This may help the patient to make an informed decision about her treatment and improve compliance with treatment. Often, patients can become disillusioned with the expected outcome of treatment and this directly affects motivation and compliance that are paramount to the success of certain treatments. Regular assessment, good communication, and patient education are key skills for CNs to ensure that patients are making informed choices about their care and management. This is set out in The Code [24], which advises nurses to act as an advocate for those in their care, helping them to access relevant health and social care, information, and support. This will aid not only in maximizing compliance but also in overall patient satisfaction through their continence care package.

Table 41.5 Educational Responsibilities of Nurses Specializing in Continence Care

- Be involved with other members of the team in the assessment, planning, delivery, and evaluation of initial education to patients, their families, and carer about incontinence.
- Be involved in providing continuing education for all patients with incontinence and planning educational programs for the area. The nurse specialist should also be involved with the team in setting, reviewing, and monitoring standards of continence care in the health district.
- Participate in the planning and delivery of education about continence care for both nursing colleagues and those working in other disciplines. This may take place in the college of nursing, university, hospital, or community.
- Act as a source of expert advice for all who cope with incontinence—including patients, other nurses, health-care staff, and agencies that work with people with incontinence (e.g., local voluntary organizations).

Table 41.6 Why Promote Compliance to Therapy

- Reduce therapeutic failure
- Reduce wastage of resources
- Cost
- Improve patient satisfaction
- Increase efficacy of service provided

Table 41.7 Reasons for Nonadherence to Treatment

- Forgetfulness
- Purpose of treatment not clear
- Perceived lack of effect
- Side effects
- Instructions for administration not clear
- Complicated regimen
- Physical difficulty in complying
- Experiences since diagnosis
- Lack of time/money
- Health-care provision

MANAGEMENT

Aside from the clinical responsibilities of CNs, many staff in these posts will also have a management role within their trust. They may be leading or actively involved in the commissioning of integrated continence services and participating in regular policy reviews on nursing issues in their service (RCN). For new services, the CNs may be drafting policies in line with evidence-based practice and setting out the aims and needs of their service by developing a service model.

In primary care, CNs may hold a budget to provide containment products for their patients and, in secondary care, may be responsible for the standardization of products across the trust. In these roles, the CNs act as buyers to negotiate the best contracts as well as accountants managing budgets and trying to make cost improvements in line with set targets. They will also have to design policies to outline those patients who are entitled to such services and how needs are assessed and standardized. In the United Kingdom, the All Party Parliamentary Group [25] has developed guidelines written by CNs for service commissioners to help guide in the development of continence services.

As part of a standard management role, the CNs will also need to be proficient in tasks such as risk assessment, quality assurance, as well as having strong leadership skills and expertise in effective staff management.

CNs also have a role in the auditing of current services to ensure that they are working in line with the current evidence base and also of identifying and assessing the needs of the service and how these can be developed.

COORDINATION OF CARE

Some patients seen in continence clinics may require input from other services. As CNs have often performed the initial assessment, it is their role to make direct referrals to these other teams and they often play a pivotal role in the coordination of care between these specialties to ensure that care is integrated and continuous. Table 41.8 lists some of the other services that continence patients may need referral too.

RESEARCH AND AUDIT

As a consequence of the advanced nursing practice within continence care, more CNs are participating in further education by completing degrees such as master’s level and even doctorate programs. As part of these courses, they are undertaking innovative and original research into the field that previously had only been completed by the doctors. CNs are often best placed to recruit patients into clinical trials as they have more direct patient contact and are the first HCP that patients will meet along their pathway. With this in mind, CNs are in an ideal place to actively promote research and can collect a multitude of data with regard to initial presentation of symptoms, epidemiology, etiology, success of conservative and pharmaceutical management, and other aspects of care.

Table 41.8 Examples of Additional Services Needed by Continence Patients

- Urogynecologists
- Gynecologists
- Urologists
- Colorectal surgeons

- Gastroenterologists
- Geriatricians
- Psychologists
- Social workers
- Physiotherapists
- Occupational therapists
- Pharmacists
- General practitioners

For those who do not wish to undertake formal research, clinical audits can also be used to inform practice. For CNs with management duties, service audits may also be completed to assess how services are running, ensure that patient needs are being met, and as a scoping exercise when looking to further develop services.

COMMUNICATION

Communication is very important in the health-care setting. Smith [26] said that the ability to communicate effectively with patients, relatives, and other staff is essential if nurses are to build trusting relationships in which patients feel that they are accepted and understood. According to Payton [27], communication has two functions in health care. First, it is essential to establish and maintain effective interprofessional relationships with the patients, relatives, HCPs, and any other persons whom we come into contact with. The second function is the successful achievement of professional tasks, such as patient care, education, research, administration, supervision, and consultation. Wojnicki-Johansson [28] suggests that certain behaviors and devices have been found to facilitate and improve communication between nurses and patients such as the use of body language, eye contact, and touch. Nurses can facilitate successful and therapeutic patient contact through questioning, listening, summarizing, reflecting, paraphrasing, set induction, and closure [9]. CNs use these skills every day to assess, reassure, reduce anxiety, educate staff and patients, plan care, encourage critical thinking, liaise with other HCPs, and promote continence care.

MAINTAINING PRIVACY AND DIGNITY

In the field of continence, ensuring complete privacy and dignity can be difficult. Although basic environmental issues are often met in order for CNs to assess incontinence, we need to understand and know many personal pieces of information about the patient and often perform internal examinations. Some patients may find this information difficult to disclose to a nurse that they have never met before. It can therefore be difficult to CNs to strike a balance between protecting privacy and dignity and maintaining modesty while assessing, diagnosing, and managing incontinence. To compensate for this, every effort should be made to ensure all other areas of privacy and dignity are maintained, e.g., appropriate clinical area for review, appropriate use of chaperones during examination, and confidentiality.

CONCLUSIONS

The role of the CN does not just involve clinical care of the incontinence patient. These individuals aim to provide holistic care for patients and to act as educators and advisors to all other HCPs who encounter continence issues in their practice. As the scope of nursing practice continues to expand, CNs will further develop to meet these demands and their level of nursing expertise will increase, not only with regard to the clinical aspects of care but also in service development to ensure integrated services and optimal continence care packages for patients.

42 Behavioral Therapies and Management of Urinary Incontinence in Women

Kathryn L. Burgio

Behavioral therapies are a group of interventions that improve bladder control by teaching patients skills for preventing urine loss or changing their daily habits. In clinical practice, behavioral interventions are usually comprised of multiple components, tailored to the individual needs of the patient, the characteristics of her symptoms, and her life circumstances. Behavioral treatment programs generally take one of two approaches. One approach focuses on improving bladder function by changing voiding habits, such as with bladder training or delayed voiding. Another basic approach targets the bladder *outlet*, such as with pelvic floor muscle training and exercise. Among the techniques included in behavioral treatment programs are self-monitoring with a bladder diary, pelvic floor muscle training techniques (including biofeedback or digital teaching), pelvic floor muscle exercise regimens, active use of pelvic floor muscles for urethral occlusion (stress strategies, the knack), urge control and suppression strategies, urge avoidance strategies, scheduled voiding (including bladder training), delayed voiding, teaching normal voiding techniques, fluid management, dietary changes to avoid bladder irritants (including caffeine), weight loss, and other lifestyle changes.

Although they are not curative in most patients, behavioral interventions are widely used because their efficacy is well established. They are safe and without the risks and side effects associated with some other therapies. However, they do depend on the active participation of a motivated patient and usually require some time and persistence to reach optimum benefit. Behavioral treatments have been recognized as effective by the 1988 Consensus Conference on Urinary Incontinence in Adults [1], the Guideline for Urinary Incontinence in Adults developed by the Agency for Health Care Policy and Research [2], the International Consultation on Incontinence (ICI) [3], and the American Urological Association Guideline on Diagnosis and Treatment of Overactive Bladder in Adults [4].

PATIENT EDUCATION

Because behavioral therapies are based on principles of learning, it is important that any behavioral program begin by providing basic patient education, so that she can understand the treatment process and the therapeutic goals. This education includes an explanation of the anatomy of the bladder and pelvic floor, how they function, and the mechanisms of urinary incontinence. Women need to understand that their behavioral program is based on changing their habits and learning new skills and that their results will depend on their active participation and daily practice. Further, understanding that improvement is often gradual facilitates adherence and realistic expectations about potential therapeutic outcomes.

BEHAVIORAL TRAINING AND PELVIC FLOOR MUSCLE TRAINING

Pelvic floor muscle training and exercise were first described by Margaret Morris in 1936 [5]. In her paper, she described tensing and relaxing of the pelvic floor muscles as an approach to the prevention and treatment of urinary and fecal incontinence. Pelvic floor muscle training was first popularized in the 1950s by Arnold Kegel, a gynecologist who proposed that women with stress incontinence lacked awareness and coordination of their muscles [6]. He also demonstrated that women could improve their stress incontinence through pelvic floor muscle training and exercise to improve strength and coordination [6,7]. Over the ensuing decades, this intervention has evolved both as a behavioral therapy and as a physical therapy, combining principles from both fields into a widely accepted conservative treatment for stress and urge incontinence. The literature on pelvic floor muscle training and exercise has demonstrated that it is effective for reducing stress, urge, and mixed incontinence in most outpatients who cooperate with training [8–20]. Pelvic floor muscle training and exercise is now a cornerstone of behavioral treatment for both stress and urge urinary incontinence [3].

Teaching Pelvic Floor Muscle Control

The goal of behavioral treatment for stress incontinence is to teach patients how to improve urethral closure and bladder neck support by voluntarily contracting pelvic floor muscles during whatever physical activities precipitate urine leakage. The first step in training is to properly identify the pelvic floor muscles and to contract and relax them selectively (without increasing intra-abdominal pressure on the bladder or pelvic floor). It is an essential and often overlooked step to confirm that patients have identified the correct muscles. Failure to find the pelvic floor muscles or to exercise them correctly is an important source of failure with this treatment modality. While it is easy for the clinician to give patients a pamphlet or brief verbal instructions to "lift the pelvic floor" or to interrupt the urinary stream during voiding, these approaches do not ensure that she knows which muscles to use before she is sent home to do daily exercises. Verification of proper muscle contraction can be accomplished by palpating the vagina during pelvic examination and giving her verbal feedback. Pelvic floor muscle control can also be taught using biofeedback or electrical stimulation.

Biofeedback is a teaching technique that helps patients learn control by giving them instantaneous, accurate feedback of their pelvic floor muscle activity. In his original work, Kegel used a biofeedback device he designed and named the perineometer [6]. It consisted of a pneumatic chamber (which was placed in the vagina) and a handheld pressure gauge, which visually displayed the pressure generated by circumvaginal muscle contraction. This device provided immediate visual feedback of pelvic floor muscle contraction to the woman learning to identify her muscles and monitor her practice.

Most biofeedback instruments in current use are computerized and display feedback visually on a computer monitor. Pelvic floor muscle activity can be measured by manometry or electromyography, using vaginal or anal probes or surface electrodes. Signals are augmented through the computer, and immediate feedback is provided on a monitor for visual feedback or via speakers for auditory feedback. When patients observe the results of their attempts to control bladder pressure and pelvic floor muscle activity, learning occurs by means of operant conditioning (trial and error learning). Biofeedback-assisted behavioral training has been tested in several studies, producing mean reductions of incontinence ranging from 60% to 85% [8,9,12,19–24].

A common problem encountered in learning to control the pelvic floor muscles is that patients tend to recruit other muscles, such as the rectus abdominis muscles or gluteal muscles, when they contract the pelvic floor muscles. Contracting certain abdominal muscles can be counterproductive, when it increases pressure on the bladder or pelvic floor, and therefore tends to push urine out rather than holding it in. Thus, it is important to observe for this bearing down Valsalva response and to help patients to exercise pelvic floor muscles selectively while relaxing these abdominal muscles.

Some practitioners recommend coordinated training of transversus abdominis muscles because it is thought that these muscles facilitate pelvic floor muscle contraction. This approach remains controversial, however, and a review article on this approach noted an absence of evidence for this type of training [25].

Daily Pelvic Floor Muscle Exercise

Once patients learn to properly contract and relax the pelvic floor muscles selectively, a regimen of daily practice and exercise is prescribed. The purpose of daily practice is twofold: to increase muscle strength and to enhance motor skills through practice. It has also been suggested that intensive strength training may increase resting tone and structural support of the pelvis by elevating the levator plate and enhancing the hypertrophy and stiffness of its connective tissues [26].

Exercise regimens vary considerably in frequency and intensity, and the optimal exercise regimen has yet to be determined. However, good results are generally achieved using 45–50 exercises per day [8,20]. To avoid muscle fatigue, it is usually recommended that patients space the exercises across the day, typically in 2–3 sessions per day. Patients may practice the exercises in the lying position at first, but it is important to progress them to sitting or standing positions as well so that they become comfortable and skilled using their muscles to avoid incontinence in any position.

Table 42.1 Instructions for Daily Pelvic Floor Muscle Practice

Do 45 pelvic floor muscle exercises EVERY day: 15 at a time, three times per day.

Do _____ lying down
Do _____ sitting
Do _____ standing

For each exercise, squeeze your pelvic floor muscles as quickly and as hard as you can.

Hold the squeeze for _____ seconds.

Relax completely after each squeeze for _____ seconds.

Remember to relax all the muscles in your abdomen when you do these exercises and continue to breathe normally.

To improve muscle strength, contractions should be sustained for 2–10 seconds [27,28], depending on the patient's initial ability. Exercise regimens should be individualized so that patients begin with a comfortable duration and gradually progress to 10 seconds [28]. Each exercise consists of muscle contraction followed by a period of relaxation using a 1:1 or 1:2 ratio [28]. This allows the muscles to recover between contractions. A template for individualized instructions for daily pelvic floor muscle exercise appears in Table 42.1.

One of the challenges of pelvic floor muscle training and exercise is motivating patients to adhere to the regimen and to sustain their efforts over time. It can be helpful to educate them that sustained improvement depends upon their continued exercise. Among the barriers to daily exercise are difficulty remembering to do the exercises and difficulty finding time [29,30]. To assist patients to remember their exercises, a variety of cues can be considered, including alarms or notes in prominent places in the home or car. Another approach is to teach them to integrate their pelvic floor muscle contractions into their daily lives or associate them with several daily activities. Once they are proficient, they no longer need to set time aside to concentrate on their exercises. Rather, they can do a few exercises during certain daily activities, such as taking a shower or sitting at a traffic light. Not only does this not add time to their busy schedules, but the activities eventually become cues, reminding them to exercise. This can improve adherence during active treatment and supports continued exercise during the maintenance phase when motivation tends to wane.

Using Muscles to Prevent Stress Incontinence

Although exercise alone has been known to improve urethral pressure and structural support and reduce incontinence [31], the best results seem to be achieved when patients contract their muscles consciously before and during coughing, sneezing, or any other activities that precipitate urine loss [16,26]. Initially, this new skill requires a conscious effort, but with consistent practice, patients can develop the habit of automatically contracting their muscles to occlude the urethra in situations of physical exertion. This skill has been referred to varyingly as the "stress strategy" [19], "counterbracing," "the knack" [32], perineal cocontraction, and "the perineal blockage before stress technique" [33].

Even when their muscles are weak, some women will benefit from simply learning how to control their pelvic floor muscles and use them to prevent urine loss. In one trial, women were taught to voluntarily contract pelvic floor muscles before or during a cough and demonstrated reduction in leakage after only 1 week of training [32]. Pelvic floor muscle precontraction has been recommended, not only during coughing but also during any daily activity that results in increased intra-abdominal pressure [34]. The strength that is needed to occlude the urethra and prevent urine leakage is not known, and some women will still need a more comprehensive program of pelvic floor muscle rehabilitation to increase strength in addition to learning this skill.

The literature on pelvic floor muscle training and exercise has demonstrated that it is effective for reducing stress, urge, and mixed urinary incontinence in most outpatients who cooperate with training. Systematic reviews and the ICI (2013) concluded that there is Grade A evidence for pelvic floor muscle training and that it should be offered as first-line treatment to women with stress, urge, or mixed incontinence [3,35–37].

BEHAVIORAL TRAINING FOR URGE INCONTINENCE

Historically, pelvic floor muscle training and exercise was used almost exclusively for the treatment of stress incontinence. It is now established as a central component in the treatment of urge incontinence and overactive bladder as well. Initially, it was observed that detrusor contraction could be inhibited by pelvic floor muscle contraction that was induced by electrical stimulation [38–40]. Then, in the 1980s, Burgio and colleagues demonstrated that voluntary pelvic floor muscle contraction can be used not only to occlude the urethra but also to inhibit detrusor contraction [8,20] (see Figure 42.1). Pelvic floor muscle control and exercise is taught in the same way as it is for stress incontinence. What differs is how women with urge incontinence are taught to use their muscles to manage urgency and prevent urine loss.

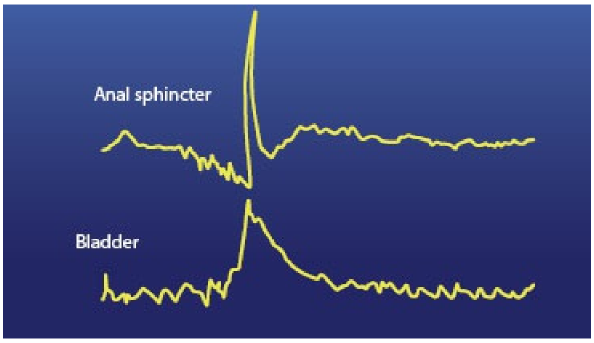

Figure 42.1 Urodynamic tracings showing detrusor inhibition associated with anal sphincter contraction.

Using Muscles to Prevent Urge Incontinence: Urge Suppression Strategies

Most patients with urge incontinence feel compelled to rush to the toilet to void. This behavior can make incontinence more likely, because it increases intra-abdominal pressure on the bladder and increases the feeling of fullness, and when the patient reaches the vicinity of the toilet, she is exposed to visual cues that can trigger incontinence. Behavioral training teaches patients a new way to respond to the sensation of urge. Although it may seem counterintuitive at first, the urge suppression strategy encourages patients to pause, sit down if possible, relax the entire body, and contract pelvic floor muscles repeatedly to diminish urgency, inhibit the detrusor contraction, and prevent urine loss. After the urge sensation subsides, they are to proceed to the toilet at a normal pace [41].

Detrusor inhibition using pelvic floor muscle contraction can be taught and documented in the clinic. A handout for teaching patients about the urge suppression strategy appears in Figure 42.2. Patients are then encouraged to practice this urge suppression technique to manage urge and prevent incontinence episodes in their daily lives.

The home program for urge incontinence follows the same daily exercise regimen as for stress incontinence. In addition, it is often helpful for women with urge incontinence to practice interrupting or slowing the urinary stream during voiding once per day. Not only does this provide practice in occluding the urethra and interrupting detrusor contraction, it does so in the context of the urge sensation, when patients with urge incontinence need it most. Some clinicians express concern that repeated interruption of the urinary stream may lead to incomplete bladder emptying in certain groups of patients. Therefore, caution is recommended when using this technique with patients who may be susceptible to voiding dysfunction.

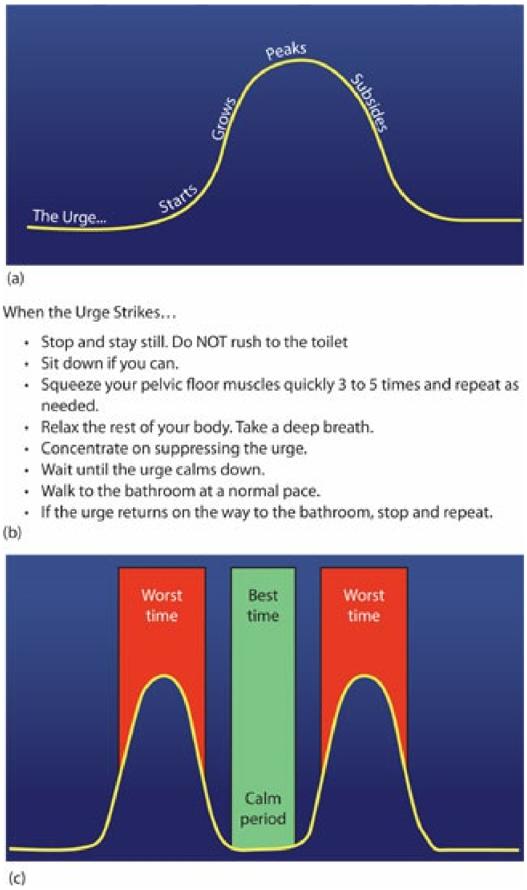
Behavioral training for urge incontinence has been tested in several clinical series utilizing pre–post designs. Mean reductions of incontinence range from 76% to 86% [8,22,24,42]. In randomized controlled trials using intention-to-treat models, mean reductions of incontinence range from 60% to 80% [20,21]. This urge suppression strategy can be combined with bladder training or delayed voiding as one of several coping techniques that can help patients postpone voiding.

VOIDING HABITS AND SCHEDULES

Decreasing Voiding Frequency

Bladder Training

It has long been thought that habitual frequent urination can over time contribute to reduced bladder capacity and lead to detrusor overactivity, which in turn causes urgency and urge incontinence. Bladder training is a behavioral intervention that was developed to break the cycle of urgency and frequency using consistent, incremental voiding schedules. When it was first introduced, it was known as bladder drill. Bladder drill was an intensive intervention, often conducted in an inpatient setting, in which women were placed on a strict expanded voiding schedule for 7–10 days to establish a normal voiding interval [43,44]. Urgency and anxiety about possible urine loss were sometimes managed with Valium. Bladder training is a sequel to this procedure that increases the voiding interval more gradually, over a longer period of time, and is conducted in the outpatient setting [45–55].



When the Urge Strikes...

- Stop and stay still. Do NOT rush to the toilet
- Sit down if you can.
- Squeeze your pelvic floor muscles quickly 3 to 5 times and repeat as needed.
- Relax the rest of your body. Take a deep breath.
- Concentrate on suppressing the urge.
- Wait until the urge calms down.
- Walk to the bathroom at a normal pace.
- If the urge returns on the way to the bathroom, stop and repeat.

Figure 42.2 (a) The urge suppression strategy. (b) Urge wave. (c) When to void. (From Burgio, K.L. et al., *Staying Dry: A Practical Guide to Bladder Control*, Johns Hopkins University Press, Baltimore, MD, 1989. With permission.)

Patients are given instructions to void at predetermined intervals, and over a period of several weeks, the voiding interval is gradually increased. This is believed to increase bladder capacity and decrease overactivity, resulting in improved bladder control. To follow this regimen, patients must resist the sensation of urgency and postpone urination. Several behavioral techniques have been used to help patients control the urge to urinate while they wait for their next scheduled void. The traditional approach has been to suggest various techniques for relaxation or distraction to another activity [52]. Patients are encouraged to distract themselves from the bladder by engaging in a task that requires mental but not physical effort, such as reading, calling a friend, or making a to-do list. Self-statements such as “I am in control of my bladder” and “I can wait” are also helpful. More recently, the urge suppression strategy (described earlier), i.e., repeated contractions of the pelvic floor muscles, has been adopted in bladder training as another way to control urgency and detrusor contractions while the patient waits to void.

Bladder training programs have differed widely in terms of the instructional approach, intensity of clinical supervision, scheduling parameters, strategies for controlling urgency, frequency of schedule adjustments, criteria for increasing the voiding interval, length of treatment, and use of adjunctive treatments. At present, there is no evidence for determining which parameters are most effective. However, the ICI recommends that clinicians should provide the most intensive bladder training supervision that is possible within service constraints [3]. Guidelines for conducting bladder training are presented in Table 42.2.

Several clinical series studies and randomized trials have demonstrated efficacy of outpatient bladder training or a mixture of inpatient and outpatient intervention [45–55]. The classic study of outpatient bladder training is a randomized clinical trial that demonstrated a mean 57% reduction in frequency of incontinence in older women [52]. In this trial, bladder training reduced not only incontinence associated with detrusor overactivity but also incontinence associated with sphincter insufficiency, possibly because patients acquired a greater awareness of bladder function or that the exercise of postponing urination increased the use of pelvic floor muscles. A subsequent trial compared bladder training to oxybutynin; 73% of women in bladder training were reported to be “clinically cured” [53].

Table 42.2 Guidelines for Bladder Training

- Review voiding diary with the patient, noting the various voiding intervals.
- Identify with the patient the longest voiding interval that is comfortable for her.
- Patient Instructions: Empty your bladder…
  - First thing in the morning
  - Every time your voiding interval passes during the day
  - Just before bed
- Teach coping strategies for occurrence of urge.
  - Self-statements (affirmations)
  - Distraction to another task
  - Relaxation
  - Urge suppression strategy (using pelvic floor muscle contraction)
- Gradually increase interval
  - When patient is comfortable for at least 3 days
  - By 30-minute intervals or clinical judgment based on patient confidence

Delayed Voiding

Another approach to helping patients to increase control and expand the interval between voids is delayed voiding. Unlike bladder training, delayed voiding does not involve putting patients on a predetermined voiding schedule. Instead, patients are taught urge suppression strategies and instructed to use them when they have an urge to void. When the urge subsides, instead of going to the bathroom immediately, they are encouraged to wait 5 minutes before voiding.

Even a mild urge to void can prompt a trip to bathroom in a woman with urge incontinence, due to the fear of urine loss. However, most patients can be convinced to try a 5-minute delay, especially when they are in safe circumstances such as at home alone. Many are surprised to find that even with a brief delay, the urge subsides or disappears altogether. This enhances their sense of control and builds confidence to gradually increase the delay time to achieve a normal frequency.

Increasing Voiding Frequency (Timed Voiding)

It is quite common for health-care providers to advise patients with incontinence to simply increase their frequency of urination as a way to avoid a full bladder and its increased risk of incontinence. While increased frequency of urination can have an immediate benefit in terms of avoiding incontinent episodes, the long-term result is most likely counterproductive because the patient can lose the ability to accommodate larger volumes and tolerate bladder fullness. In addition, it feeds the cycle of urgency and frequency thought to perpetuate overactive bladder and exacerbate urge incontinence in the long run.

Increasing the frequency of voiding is generally reserved for patients who void infrequently (<5 times per day). Infrequent voiding may reflect a lifelong pattern of urge suppression (e.g., in teachers or nurses) or can be the result of reduced bladder sensation. Often, these patients have never considered voiding more frequently because they do not have an urge to void. It may also be due to dementia or other cognitive impairments in patients who are unable to inhibit bladder contraction and unable to learn new skills for bladder control. A timed voiding schedule can prompt them to void before urgency with leakage occurs. It is possible for many patients to identify times in their day when they are at increased risk of incontinence, for example, 2 hours after morning coffee or during exercise, and they can plan strategic voids before those times.

BLADDER DIARY

The bladder or voiding diary is a widely used tool in the evaluation and monitoring of incontinence in women. It provides information on the timing of symptoms and events that helps the clinician to understand the type, severity, and circumstances of urine loss and plan appropriate components of behavioral intervention. The diary is less recognized for its value in the treatment phase when it can be reviewed periodically to track the efficacy of various treatment components and guide the intervention. In research, it provides a validated measure of the frequency of voids and incontinence episodes and has also been used to measure the number and severity of urgency episodes.

In addition to its value for the clinician, completing a daily diary can have direct benefit to the patient. Its self-monitoring effect enhances the patient's awareness of voiding habits and patterns of incontinence. It encourages patients' recognition of how their incontinence is related to their activities, for example, their physical activities or drinking patterns. In particular, understanding clearly the immediate precipitants of urine leakage optimizes the patient's vigilance and readiness to implement the continence skills learned through behavioral treatment.

To have a reliable sample of the patient's habits, it is useful for her to complete a diary for 5–7 days [56]. At a minimum, she should record the time of each incontinent episode and the circumstances or reasons for the urine loss [41]. In behavioral treatment, the circumstances of each incontinent episode noted in the diary can be reviewed with the patient and used to develop instructions that are specific to that patient's situation. Through the process of reviewing the bladder diary, patients can identify certain times when they are more likely to have incontinence and activities that seem to trigger incontinence. Most commonly, patients can be made more aware of the antecedents of stress incontinence (e.g., coughing, sneezing) and develop the habit of contracting their pelvic floor muscles in preparation for these situations.

In addition to documenting incontinence, it is also very useful to have the patient record the times she urinates both during the day and at night. These recordings can be used to identify patients who urinate too frequently and to establish appropriate voiding intervals for interventions like bladder training and delayed voiding. A record of voided volumes provides a practical estimate of the patient's functional bladder capacity in their daily lives. Because it is more burdensome to measure voided volumes, they are usually collected for only 24–48 hours.

There are many different formats for bladder diary in use. One example of a bladder diary form is presented in Figure 42.3. The form should be modified as needed to collect information most pertinent to each patient's symptoms. For example, columns can be added as needed to record voided volumes and type and volume of fluid intake, in order to identify polydipsia as a cause of lower urinary tract symptoms.

Many clinicians are skeptical of the bladder diary, partly because of reports that patients have not completed them in real time, but rather just before the visit in the waiting room. Despite these anecdotes, we have observed that most patients are capable of using the diary correctly if they are educated about its purpose and how it will be used. Sending a blank diary to patients along with other routine forms in preparation for their first visit may not accomplish this. To improve the chances of obtaining a useful diary, it is best to look at the diary with the patient in person, review its parts, and explain how and when to fill it out. Patients should be encouraged to carry the diary with them at all times and to make entries as soon as it is feasible. Some patients prefer that the diary be small enough to fit in a purse. Alternatively, they can be given explicit permission to fold it. Further, it seems to be helpful to tell the patients that it is okay to get it dirty or spill on it, such that we expect to see coffee stains and ragged edges.

Figure 42.3 Sample bladder diary.

Equally important is how the diary is handled when the patient returns it to the clinician. If we merely collect the diary and put it in the chart, we can devalue this carefully collected information in the patient's eyes. If she does not believe that her diary entries will be used to understand her condition and inform decisions about her treatment, she is not likely to put effort into daily recording in the future. If the clinician takes an interest in her diary entries by reviewing each day's events, we communicate that the information is useful in guiding her treatment, and this encourages continued accurate recordings.

LIFESTYLE CHANGES

Lifestyle changes are generally used as adjuncts to a primary behavioral intervention in selected cases. Lifestyle changes include fluid management, caffeine reduction, weight loss, avoiding bladder irritants, and bowel management.

Fluid Management

Fluid management is a common practice used to make it easier for patients to control their bladders. Assessment may involve the patient completing a fluid intake diary, and recommendations include alterations in the volume or type of fluids that patients consume. Many patients with incontinence restrict fluid intake as a self-management technique to help prevent incontinence by avoiding bladder fullness. In some cases, particularly among older women, this results in an inadequate intake of fluid and places them at risk of dehydration. It is important to recognize these cases and encourage patients, for their overall health and well-being, to consume an adequate amount of fluid each day, such as the often recommended 6–8 glasses of fluid each day [57]. It is thought by some clinicians that this will also dilute the urine making it less irritating to the bladder.

It should be noted that avoiding fluid intake in the evening hours can be helpful for reducing nocturia. Similarly, it can be very helpful for some patients to restrict fluids for a time when toilet access will be limited, such as before a church service. Women using such targeted fluid restriction should be reminded to compensate for these missed fluids earlier or later to ensure that their total daily fluid intake is adequate.

In patients who consume an abnormally high volume of liquids, fluid restriction is often appropriate. Some patients maximize their fluid intake deliberately in the belief that they need to "flush" their kidneys, to avoid dehydration, or in an effort to lose weight. It is not uncommon to see women carry a water bottle throughout the day taking frequent drinks for health reasons. In these cases, reducing excess fluids can relieve problems with sudden bladder fullness and urgency.

Caffeine Reduction

Caffeinated beverages in particular can exacerbate incontinence because in addition to its diuretic effect, caffeine is a bladder irritant for many people. Research has demonstrated that caffeine increases detrusor pressure [58] and that it is a risk factor for detrusor instability [59,60]. Evidence also exists that reducing caffeine intake helps to reduce episodes of incontinence [61–63].

Although it is very difficult for most coffee drinkers to completely eliminate it from their diet, provided with the knowledge that caffeine may be aggravating their incontinence, many will be willing to reduce their intake or to eliminate it for a few days as a trial. Reducing caffeine intake can be done gradually by mixing decaffeinated beverages with caffeinated beverages in increasing increments. For example, coffees can be mixed to consist of ¼ decaffeinated coffee in week 1, ½ in week 2, ¾ in week 3, and full decaffeinated coffee in week 4.

Avoiding Bladder Irritants

Many clinicians recommend, even as a first-line approach, restricting certain foods and beverages that are believed to irritate the bladder, including sugar substitutes, citrus fruits, spicy foods, and tomato products. Although there is little scientific evidence on dietary factors, there are many cases in which these substances appear to be aggravating incontinence, and reducing or eliminating them has provided clinical improvement. A diary of food and beverage intake can sometimes be useful in identifying which substances are irritants for individual patients. Rather than recommending that all patients restrict their intake of these substances, a diary or trial restriction can help to identify which patients are sensitive and may chose to reduce their intake.

Weight Loss

Obesity is an established risk factor for urinary incontinence. Women with higher body mass index are not only more likely to develop incontinence, but they also tend to have more severe incontinence than women with lower body mass index. Research on the relationship between body mass index and incontinence reports that each five-unit increase in body mass index increases the risk of daily incontinence by approximately 60% [64,65].

Intervention studies of morbidly obese women report significant improvement in symptoms of incontinence with weight loss of 45–50 kg following bariatric surgery [66–68]. Similarly, significant improvements in continence status have been demonstrated with as little as 5% weight reduction in more traditional weight loss programs [69]. The most definitive randomized trial of weight loss for incontinence was the Program to Reduce Incontinence with Diet and Exercise (PRIDE) study. PRIDE compared an intensive 6-month group-administered, weight loss program of diet, exercise, and behavioral modification to a structured education control program in overweight and obese women with incontinence [70]. Both groups received a booklet describing a step-by-step self-administered behavioral program to reduce incontinence. The weight loss program, which resulted in a mean weight loss of 8%, showed significantly greater reductions in number of incontinence episodes compared to the control group, which had a mean weight loss of 1.6% (47% vs. 28%).

Because moderate weigh loss is an achievable goal for many women, it is rationale to recommend weight loss as a first-line treatment or as part of a comprehensive program to treat incontinence in overweight and obese women.

Bowel Management

Fecal impaction and constipation have been cited as factors contributing to urinary incontinence in women, particularly in nursing home populations [71]. In severe cases, fecal impaction can be an irritating factor in overactive bladder or obstruct normal voiding, causing incomplete bladder emptying and overflow incontinence. Disimpaction relieves symptoms for some patients, but it can recur in the absence of a bowel management program. Bowel management may consist of recommendations for a normal fluid intake and dietary fiber (or supplements) to maintain normal stool consistency and regular bowel movements. When hydration and fiber are not enough, stool softeners or enemas may be used to stimulate a regular daily bowel movement, preferably after a regular meal such as breakfast to take advantage of postprandial motility.

ENCOURAGING PATIENT PARTICIPATION AND ADHERENCE

Most behavioral therapies for incontinence are based on self-management models, and their success depends on the active participation of a motivated patient. This reliance on patient behavioral change is perhaps the main limitation of this treatment approach. Like any new habit or skill, changing daily bladder habits and learning new skills require effort and persistence over time. It can be challenging for women to remember to use their muscles strategically in daily life as well as to maintain a regular exercise regimen for strength and skill. Unlike with some therapies, progress with behavioral treatment is often gradual. This gradual change makes it difficult for patients to appreciate even steady improvement over time and represents the primary challenge for behavioral treatment—how to sustain the patient's motivation for a long enough time that she will experience noticeable change in her bladder control.

A key ingredient in addressing this challenge is to maintain contact with the patient during this period of time when her benefit is not yet appreciable. Rather than leaving the patient on her own, it is essential that clinicians support the patient's efforts to persist by scheduling follow-up appointments to review and reinforce her progress, encourage persistence, identify and address barriers, and make any needed adjustments to her daily regimen. In addition, when initiating behavioral treatment, it is important to make it clear to the patient that her improvement, as with any new skill, will likely be gradual, with good days and bad days, and that it will depend on her consistent practice. The patient who expects this course of treatment will be better prepared to persist over time so that results can be achieved and maintained long term.

Little research has examined the durability of behavioral treatments in the long term, but studies are promising in that many patients are able to sustain improvements in bladder control over time [72–74].

WHO IS A CANDIDATE FOR BEHAVIORAL THERAPY?

Most patients who engage actively with behavioral treatment for incontinence experience some degree of improvement, yet there is considerable variation in outcomes. Little is known to help us predict which patients will respond best to behavioral treatment. Most studies examining predictors of success have found that outcomes are not related to the type of incontinence or urodynamic diagnosis [13,52,55,75,76]. Some studies show that patients with more severe incontinence have greater improvements [52,72], but others conclude that patients with more severe incontinence have poorer outcomes [22,72,76] or no relationship between severity and outcome [24,55,75,77]. Evidence on the effect of age is also inconsistent [22,24,52,77]. Current evidence indicates that outcomes are not associated with patient race, parity, body mass index, cystocele, uterine prolapse, hysterectomy, hormone therapy, use of diuretics, or urodynamic parameters [76]. There is little information in the usual clinical evaluation of a patient with incontinence that would indicate the likelihood of her success or failure with behavioral treatment. Thus, given that behavioral therapies are virtually without risk and most adherent patients experience symptom improvement, offering behavioral treatment as first-line therapy is appropriate for any woman with urinary incontinence.

43 Physiotherapy for Urinary Incontinence

Bary Berghmans

INTRODUCTION

Worldwide, urinary incontinence is a common and distressing health problem with often huge social consequences. In Western countries approximately 10% of all adult women report leakage at least weekly [1]. Increasing prevalence of 20%–30% during young adult life to 30%–40% around the menopause to 30%–50% in the elderly has been reported by some authors [2,3]. Others report a prevalence of any urinary incontinence of 22% [4] to 29% [1] in older women, severe urinary incontinence in 7% [1]. Among nursing home residents, this percentage increases to 42%–72.5% [4,5]. Urinary incontinence is associated with nursing home admission from the community [6].

Although there is no consensus yet about what constitutes significant urinary incontinence [7], incontinence is predominantly a problem among women: 10% of them suffer from weekly incontinence, 25%–45% from occasional leakage [7]. Pooled overall prevalence rates in men are from 4.81% to 32.17%, with the prevalence increasing with age [1,8].

The annual incidence of "monthly" or "any" urinary incontinence varies between 1% and 19%, for "weekly" urinary incontinence between 1.2% and 4% [1], and the yearly remission is reported between 2% and 5% [1].

Mainly due to shame, taboo, and unawareness of treatment possibilities, only a minority of people suffering from incontinence seek professional help [9,10]. In daily general practice, patients usually go for help when the loss of urine leads to mental, physical, or social problems or discomfort for the patient or his or her social environment. Because of more and better patient information, in the Netherlands now about half of the women suffering from urinary incontinence consult a medical doctor [10].

Several forms of urinary incontinence such as stress incontinence, mixed incontinence, and incontinence due to detrusor overactivity (DO) can be differentiated [11]. Symptoms of the latter are urgency, frequent micturition, nocturia, and/or urgency incontinence [11].

In women, the most prevalent form is stress incontinence, being responsible for 49% of all cases of isolated stress urinary incontinence (SUI) [1]. Isolated urgency urinary incontinence is the second most prevalent cause of urinary incontinence (1%–7%) [1]. Combinations of the aforementioned symptoms of stress and urgency incontinence are considered to reflect mixed incontinence [12]. Its prevalence is 7.5%–25% [1].

A patient suffering from stress incontinence usually has a normal voiding frequency (less or equal than eight times in 24 hours) and bladder volume and has mean micturitions between 200 and 400 cc/void, but with neither urgency nor micturition. The patient generally complains of losing small amounts of urine during exertion.

A patient with urgency incontinence usually loses more urine (up to the complete content of the bladder) than a patient with stress incontinence. On the other hand, the patient may void less than 150 mL urine during micturition, suggesting a reduced functional capacity of the bladder.

Incontinence has several treatment options such as physiotherapy, drug treatment, and surgical procedures. Most patients can be treated to a satisfactory level [13]. In several countries, guidelines have been published [13–20]. For the time being, little is known about the implementation of these guidelines and their use in daily practice [16].

For patients with incontinence, physiotherapy is often considered as first-line treatment due to its noninvasive character, the results in terms of symptom relief, the possibility of combining physiotherapy with other treatments, the low risk of side effects, and the moderate to low costs. Important restrictions are that the success depends on the motivation and perseverance of both the patient and the physiotherapist and the time needed for therapy [16].

In this chapter, we review and discuss the diagnosis, analysis, evaluation, and therapeutic possibilities of physiotherapy for stress incontinence, urgency incontinence, and mixed incontinence.

MEDICAL DIAGNOSIS

For women with urinary incontinence, the International Consultation on Incontinence (ICI) distinguishes between initial management and, in case of failure, specialized management [21,22]. For initial management, the ICI (2013) recommends a simple clinical assessment leading to a *presumed* medical diagnosis. First-line health-care providers such as general practitioners (GPs) should use simple diagnostic tools like structured history taking; micturition or voiding diaries (to assess drinking habits, voiding pattern, type, pattern and volume of urine loss, impact), filled in by the patient; and physical examination [23–25]. To help the GP to improve his or her accuracy of medical diagnosis, also short questionnaires for the triage of women with urinary incontinence to quickly differentiate between stress, urgency, and mixed incontinence are developed and methodologically tested [26]. An example of such a questionnaire is the two-item Stress/Urge Incontinence Questionnaire (S/UIQ) [26].

S/UIQ and Classification System

S/UIQ

1. How many times in the last 7 days have you had an accidental leakage of urine onto your clothing, underwear, or pad during an activity such as coughing, sneezing, laughing, running, exercising, or lifting?
2. How many times in the last 7 days have you had an accidental leakage of urine onto your clothing, underwear, or pad with such a sudden strong need to urinate (United States)/pass water (United Kingdom) that you could not reach the toilet in time?

Incontinence Symptom Classification System with S/UIQ

- SUI ≥ 4; UUI = 0 pure SUI
- SUI > 0; SUI > UUI; UUI > 0 stress predominant mixed urinary incontinence
- SUI > 0; SUI = UUI balanced mixed urinary incontinence
- SUI > 0; UUI > 0; UUI > SUI urge predominant mixed urinary incontinence
- UUI ≥ 4; SUI = 0 pure urge urinary incontinence

SUI, stress urinary incontinence episodes per week; UUI, urge urinary incontinence episodes per week.

For the GP, who, in many countries throughout the world, is the first physician the patient is referred to for consultation, the use of these simple tools still associated with difficulty in finding the exact cause of the urinary incontinence. Specialists, like the urologist or the gynecologist may fall back on specific diagnostic tests such as urodynamic evaluation.

Usually, GPs have no access to such tests, and therefore, GPs must rely on their history taking, physical examination, and questionnaires like the S/UIQ.

However, because of its invasive character and doubts about its usefulness, reliability, and validity, the need for urodynamic testing is currently being discussed. Recent high-quality evidence showed that, even in cases of surgery for women with *uncomplicated*, demonstrable SUI, preoperative office evaluation alone was not inferior to evaluation with urodynamic testing for surgical outcomes at 1 year [27].

This suggests that for GPs urodynamic tests are—by and large—only needed if there is doubt about the type of incontinence and, consequently, about the necessity and choice of treatment.

These suggestions are supported by reports concluding that under optimal conditions (after GP training), the sensitivity and specificity of the GPs history taking and physical examination to detect urodynamic stress incontinence are 78% and 84%, with a positive predictive value of 87% [24]. Using simple diagnostic tools such as the S/UIQ, these percentages even can be enhanced [22]. A meta-analysis of primary care diagnostic methods of urinary incontinence (initial management) showed a sensitivity of 0.92 (95% confidence interval [CI] 0.91–0.93) and a specificity of 0.56 (0.53–0.60) to correctly identify women with urodynamic stress incontinence [28]. A clinical history for the diagnosis of DO was found to be 0.61 (0.57–0.65) sensitive and 0.87 (0.85–0.89) specific [28].

Unfortunately, in busy daily practice, and for these variably trained GPs, such optimal conditions can usually not be maintained over a prolonged period of time. Moreover, the symptoms of incontinence may be vague and less clear-cut as compared to that which is written in textbooks. Altogether, this may impair the reliability of history taking and physical examination [13].

In case of a referral to a pelvic physiotherapist, an as accurate as possible medical diagnosis is very important to determine the severity and impact of the complaints of the patient and to estimate the success or failure aspects of pelvic floor physiotherapy [29]. But in the initial management of urinary incontinence in women, in a lot of cases, the *presumed* medical diagnosis lacks accuracy, confronting the physiotherapists with heterogeneity or complexity of indications and unclear grade of severity, which might result in a minor degree of success or even failure.

Probably because of its unpredictable prognosis and appearance of symptoms, like losing all content of the bladder because of irresistible urgency, urgency incontinence due to DO has a greater impact on quality of life than stress incontinence [30–32].

Especially younger people describe DO as very intrusive [33,34].

After a childbirth, stress incontinence sometimes goes together with a total denervation of the pelvic floor muscles or with great damage to surrounding connective and structural tissue.

In such cases, physiotherapy has normally little or no effect.

Also in patients with DO as a result of an infection or a spinal cord lesion, the effect of physiotherapy is not likely to be satisfactory [35].

Next to pregnancy and birth dysfunction, incontinence can also develop as a result of a neurological problem and/or a trauma. For the majority, the pathophysiology of the health problem(s) determine(s) prognosis and result of treatment [36,37].

Whether or not there is a causal relationship between the grade of pelvic organ prolapse (POP) and (stress) urinary incontinence has yet to be determined. Some authors consider that POP and SUI share similar pathophysiologies and might be etiologically connected [38]. DeLancey et al. (2007) showed, in a study of 151 women with prolapse and 135 controls with normal support determined by POP quantification examination, that women with prolapse have reduced pelvic floor muscle strength and generated less vaginal closure force during pelvic muscle contraction than controls, potentially leading to urinary incontinence [39].

Hagen et al. (2004) reported that, in the United Kingdom, physicians referred a number of women with a presumed diagnosis of both POP and urinary incontinence to the pelvic physiotherapist and that 92% of the physiotherapists assessed and treated the combination of these two pelvic floor dysfunctions [40]. Although there are no guidelines for the treatment of POP available so far, more recent randomized clinical trials (RCTs) show that, compared to no treatment, pelvic physiotherapy is effective in women with POP (stages I–III) of any type and urinary incontinence [41–43].

Also, other etiological and prognostic factors such as age, hysterectomy, estrogen depletion during menopause, chronic diseases such as diabetes mellitus, immobility, obesity, and number, duration, and mode of delivery play a role in incontinence [43].

In the Royal Dutch Society for Physiotherapy (KNGF) guidelines on adult SUI, a systematic review of the literature up to 2011, including only prospective studies, has been included [16]. Thirty-nine studies were found to meet the inclusion criteria. Using the Evidence-Based Richtlijn (Guideline) Ontwikkeling (Development) (EBRO) criteria, these studies were first evaluated in terms of quality [16]. The conclusions were that it has been demonstrated (level of evidence A2) that there is an increased risk of SUI after pregnancy if SUI was already present before the pregnancy [44] and after the pregnancy if SUI was present during the pregnancy [45]. Similarly, there is an increased risk of developing SUI after vaginal delivery [46]. The risk of developing SUI rises with the age of the mother at the time of her first delivery [46]. If a woman has SUI 3 months after giving birth, there is an increased risk that she will also have SUI later on [44]. The risk of developing SUI increases with increasing BMI (>25) [47] and among morbidly obese women (BMI > 30) [48]. More details on etiological and prognostic factors of success of pelvic physiotherapy can be found in the KNGF guidelines [16]. If, and to what extent, there is a causal relationship between these factors and the incidence of incontinence is by far not clear yet [49,50].

Still, identification of relevant etiological and prognostic factors that might hinder—locally and/or in general—recovery and compensation and whether or not these factors can be influenced by physiotherapy is important, because these might have consequences for the strategy, routing, and outcome of treatment.

So, following relevant guidelines recommendations, the referral to a pelvic physiotherapist should contain the following data [16]:

- Date of referral and personal patient data
- An as accurate as possible medical diagnosis
- Severity of urine loss and patient's experience and impact of the complaints of the patient
- Diagnostic findings: capacity to contract, either voluntarily or involuntarily, and relax the pelvic floor muscles and indication of (level of) pelvic floor muscle strength
- Presence of and grade of prolapse and/or other relevant urogynecological health problems
- Data of the voiding diary
- Requested intervention and, if applicable, former interventions
- Potential (causal) (risk) factors and prognostic factors (e.g., rupture after vaginal delivery, a neurological damage of the pudendal nerve, diabetes mellitus, earlier urogynecological surgery)
- Use of medication (related to incontinence interfering with treatment)

PHYSIOTHERAPEUTIC DIAGNOSTIC PHASE

Based on the medical diagnosis of the referring physician, the physiotherapist starts his or her physiotherapeutic diagnostic process. The aim is to assess, analyze, and evaluate the—often unclear [16]—nature and severity of the urinary incontinence problem and to determine whether and to what extent a physiotherapeutic intervention can be effective. What is the nature of the underlying pathology? Are there any local or general obstructing factors for recovery and improvement, and to what extent can these factors be influenced by physiotherapy?

Using the International Classification of Functioning [50] (Table 43.1), the physiotherapist tries to influence the *consequences* of the health problem on three different levels: organ level (impairment level, e.g., urine loss while coughing), personal level (disability level, e.g., sanitation), and social–societal level (restriction of participation, e.g., social isolation).

The taking of a systematic history aims to establish and record

- The confirmation of the type of incontinence (Is it really a case of stress urinary incontinence?) (See Table 43.2)
- The severity of the health problem by noting impairment(s), disability(ies), and restrictions in participation
- The likely nature of the underlying pathology by noting causal factors (e.g., in stress incontinence trauma during vaginal delivery[ies])
- Local factors, which may prevent the recovery and improvement (e.g., prolapsed uterus)
- General or systematic factors, which may prevent recovery and improvement (e.g., diabetes mellitus)
- Personal factors (e.g., what efforts does the patient make to alleviate stress or urgency incontinence)

The type of incontinence will become clear during history taking and can, if necessary, be confirmed using the incontinence questionnaire (3IQ) test. A presumptive diagnosis of SUI can be established using a short questionnaire for primary care, which allows rapid and valid discrimination of the main types of urinary incontinence, for example, SUI vs. urgency (urinary) incontinence.

Table 43.1 Definitions of the International Classification of Functioning Terms: Impairment, Disability, and Restriction in Participation

Impairment	Loss or abnormality of psychological, physiological, or anatomical structure or function at organ level. With respect to the classification of disorders in the storage and voiding of urine and feces, this means the impairment stress incontinence, or detrusor overactivity.
Disability	Restriction or loss of ability of a person to perform functions/activities in a normal manner. With respect to the classification of disabilities of voiding and stool, this means the disability involuntary loss of urine.
Restriction in participation	Disadvantage due to impairment or disability that limits or prevents fulfillment of a normal role (depends on age, sex, sociocultural factors) for the person.

Source: WHO-Publication, *International Classification of Functioning, Disability and Health* (*ICF*), World Health Organization, Geneva, Switzerland, 2001.

Table 43.2 3IQ Test

During the last 3 months, have you leaked urine (even a small amount)?

Yes (please continue with questions 2 and 3) or no (questionnaire completed).

During the last 3 months, did you leak urine (check all questions that apply)?

1. When you were performing some physical activity, such as coughing, sneezing, lifting, or exercise?
2. When you had the urge or the feeling that you needed to empty your bladder but you could not get to the toilet fast enough?
3. Without physical activity and without a sense of urgency?

During the last 3 months, did you leak urine most often (check only one)?

1. When you were performing some physical activity, such as coughing, sneezing, lifting, or exercise?
2. When you had the urge to empty your bladder but you could not get to the toilet fast enough?
3. Without physical activity and without a sense of urgency?
4. About equally as often with physical activity as with a sense of urgency?

Definitions of type of urinary incontinence are based on the responses to question 3:

1. Most often with physical activity → stress only or stress predominant urinary incontinence
2. Most often with the urge to empty the bladder → urgency only or urgency predominant urinary incontinence
3. Without physical activity or sense of urgency → other cause
4. About equally with physical activity and sense of urgency → mixed urinary incontinence

The 3IQ test is a useful measurement instrument, which can establish the presence of SUI with a sensitivity of 0.86 (95% CI = 0.79–0.90) and a specificity of 0.60 (95% CI = 0.51–0.68) and can establish urgency (urinary) incontinence with a sensitivity of 0.75 (95% CI = 0.68–0.81) and a specificity of 0.77 (95% CI = 0.69–0.84) (Table 43.2) [51].

A physical examination of the patient is important in order to verify and support the patient profile gained from the patient's history. To conduct the physical examination, a number of diagnostic tests are available to the physiotherapist. The severity of the stress, urgency, or mixed incontinence depends not only on the condition of the pelvic floor and the bladder but also on the posture, respiration, movement, and the general physical and psychological condition [52,53]. Information on the severity of stress, urgency, or mixed incontinence can also be obtained by studying the voiding diaries mentioned earlier with relevant data about incontinence. Also subjective self-report, quality-of-life questionnaires, and/or symptom questionnaires, such as the "PRAFAB"-score (which combines the most important objective and subjective elements of the degree of urinary incontinence), are helpful [54]; *p*rotection (use of pads), *a*mount of urine loss, *f*requency of the complaint, *a*djustment in behavior due to the complaint, and *b*ody image as a result of the urine loss are the five elements of the PRAFAB-score. With such questionnaires, it is possible to illustrate the degree of incontinence in a reproducible manner [54]. Especially in patients with stress incontinence, a pad test can be useful to test the extent and severity of the involuntary loss of urine [55].

The objective of physical examination is to understand

- The functionality of the pelvic floor in rest and during activities in terms of coordination, tonus, endurance, and strength
- The possibility and degree of contraction (with or without awareness) and relaxation of the pelvic floor muscles
- The influence of other parts of the body on the function of the pelvic floor, by inspection at rest and while moving

For qualification and quantification of strength of contraction, level of relaxation, coordination, endurance, repeatability, and displacement, manual assessment of the function of the pelvic floor muscles is the most commonly performed technique by physiotherapists. It is done either by digital intravaginal (Figures 43.1 and 43.2) or intra-anorectal palpation with the patient in supine position [16]. To test maximal strength, the patient is instructed to contract the pelvic floor muscles as hard as possible. Muscular endurance is tested by asking the patient to sustain a near to maximum contraction for at least 10 seconds repeatability to repeat as many as possible maximal contractions followed by complete relaxation during 15 seconds. Digital palpation is also used to determine pelvic floor muscle (over, under) activity, pelvic floor muscle activity differences and differences between the left and the right side of the pelvic floor (Figure 43.3).

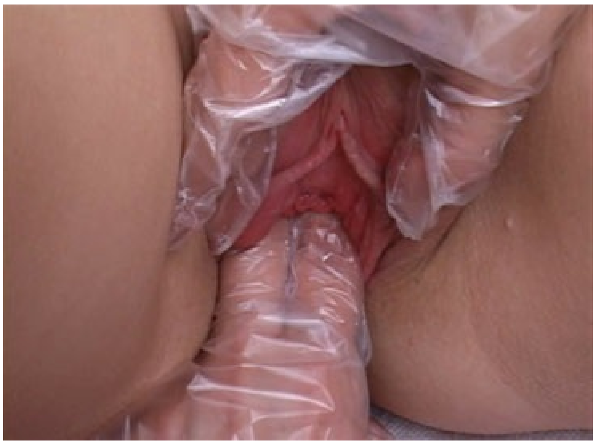

Figure 43.1 Assessment of the pelvic floor and contraction of the levator ani muscles.

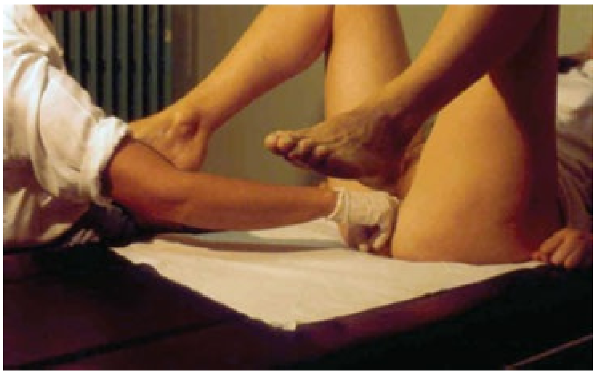

Figure 43.2 Pelvic floor muscle training for stress urinary incontinence (and mixed urinary incontinence [MUI] with predominant stress factor): (1) explain correct PFM contraction; (2) practice before checking ability to contract; (3) first intensive guidance in office to perform conscious and selective PFM contractions to prepare for pelvic floor muscle training [PFMT] at home; (4) set up individual home training program; (5) follow up with weekly or more often supervised training. The first part of PFMT can involve digital palpation to support and control PFM contractions during coughing and lift of one or two legs (as shown), followed by more functional exercises such as lifting weights, sitting down, or standing up. (By kind permission of IRPP, Lille, France.)

With pelvic floor muscle palpation, vaginal squeeze pressure and inward/upward lift of the pelvic floor muscles can be registered. For assessment of contraction of the levator ani muscles, the pelvic physiotherapist inserts first his or her index, if possible followed by his or her middle finger from below inside the vagina until he or she feels the levator ani muscles.

To assess a conscious contraction, the patient is instructed to contract the pelvic floor muscles (“withhold a flatus; contract the anus inward; stop the urine”). An unconscious contraction (the pelvic floor muscles [PFM] contraction that takes place preceding an abdominal pressure rise, for instance, due to a cough, to prevent loss of urine, sometimes called reflex contraction) is assessed by asking the patient to (deeply) cough and to perform a Valsalva maneuver. In all cases, a correct contraction is a simultaneous circumferential squeeze around the physiotherapist’s index or index and middle finger and inward/upward movement or elevation of the levator ani muscles. To quantify the (static and dynamic) strength of a voluntary or reflex contraction, the International Continence Society and the International Association of Urogynecology recommend the use of the tool in Figure 43.3 [11].

The strength of the PFM contraction is graded as

- Absent, no contraction at all
- Weak, i.e., weak contraction (pelvic floor [PF] lift not possible)
- Normal, i.e., moderate contraction (PF lift is possible)
- Strong, i.e., good contraction (PF lift is possible)

Pelvic floor muscle relaxation should be tested after a contraction. Therefore, the investigator should always start with a contraction and then ask for relaxation. Relaxation is graded as absent, partial (i.e., incomplete and/or delayed), or complete (Figure 43.2).

The strength of the pelvic floor muscles can also be measured by a vaginal squeeze pressure device connected to a manometer (pressure manometry, perineometer) [56] or pelvic floor dynamometer (a kind of strain gauge device for the pelvic floor to measure precisely forces produced during a pelvic floor muscle contraction independently of the evaluator's judgment) [57]. These methods are complicated to perform, demand clinical experience and skills in order to produce a methodologically high-quality result or are not yet clinically available [58].

More recently, an increasing number of pelvic physiotherapists assess pelvic floor function with perineal ultrasound. Dynamic evaluation of pelvic floor function includes position and elevation or descent of the bladder neck. Also, the puborectalis muscle at rest as well as pelvic floor precontraction, voluntary pelvic floor maximal and submaximal contractions, hold during respiration and sneezing or coughing, stabilization of the urethra, and hold of bladder neck position during coughing or abdominal maneuvers can all be evaluated. However, although pelvic floor imaging using ultrasound becomes more and more popular, diagnostic ultrasound is reported to be well known for its operator-dependent nature and should only be used after appropriate and effective education [59].

A limitation of the different measurement methods common to all clinic-based measurements of pelvic floor muscle function is that they are performed in the supine position or other standard positions. One should keep in mind that this might not reflect functional or usual activity of the pelvic floor during daily life activities as a response to increased abdominal pressure [58].

After the history taking, physical examination, and functional tests, analysis and evaluation of the results of physiotherapeutic diagnostic phase and relevant medical data will complete this process. The diagnosis of the referring provider can be confirmed or changed, and the indication for physiotherapy ascertained. Therefore, answering the following questions is necessary:

- Is referral diagnosis likely?
- Are there any urinary incontinence–related health problems?
- What is the nature of the stress incontinence, urgency incontinence, or mixed incontinence?
- What is the severity and the extent of the health problem?
- Is there a dysfunction of the pelvic floor?
- What caused this dysfunction?
- Are there currently any local factors that may prevent recovery or improvement, and can physiotherapeutic intervention have an influence on these factors?
- Are there any general factors that may prevent recovery or improvement?
- Is physiotherapy indicated?

In terms of total time and number of treatment sessions

It is important to take into account other prognostic and patient variables, such as age, obesity, and vaginal childbirth, which will have their impact on the process of intervention.

In Table 43.3, a flowchart for the referral and physiotherapeutic diagnostic process is given.

INTERVENTION PHASE

As a general rule, the least invasive and the least troublesome treatment procedure should be considered as a first choice. After analysis and evaluation, the physiotherapist formulates his treatment plan. He or she estimates whether full recovery can be achieved or only compensation of the complaints is possible. Also, he or she determines his or her strategy, procedure, methods of treatment to reach the goal, and whether or not he or she has the skills and capability to do the job.

Approach and treatment modalities will be different for patients with stress incontinence, DO, or mixed incontinence, but all these low-risk interventions involve educating the patient and providing positive reinforcement for effort and progress [17,43].

Patient education embraces all relevant concepts (e.g., what is the function of the bladder) and information for the patient. Comprehension on the part of the patient will promote the motivation to start on other stages of treatment. The interplay between patient and physiotherapist is very important in this process. Before starting the specific therapy modalities on the pelvic floor, it is important to know and appreciate the position and the function of the pelvic floor and how to contract and relax the pelvic floor muscles. To achieve satisfactory results from intervention (in the long term), information and supervision by the physiotherapist throughout the intervention phase are essential, especially concerning the adequate use of the pelvic floor muscles during daily life activities and efforts and behavior of micturition.

Stress Urinary Incontinence

Physiotherapeutic treatment modalities for SUI are PFMT with or without biofeedback, electrical stimulation, magnetic stimulation, and/or vaginal cones.

The biological rationale for PFMT in the management of stress incontinence is that a strong and fast pelvic floor muscle contraction will clamp the urethra, increasing the urethral pressure, to prevent leakage during an abrupt increase in intra-abdominal pressure [60]. If the pelvic floor muscles are normally innervated and sufficiently attached to the endopelvic fascia, and, if by contracting her pelvic muscles before and during a cough, a woman is able to decrease that leakage [61], then simply learning when and how to use her pelvic muscles may be an effective therapy. In such cases, the subject needs to train to use this skill during those activities that transiently increase abdominal pressure [62]. DeLancey has also suggested that an effective pelvic floor muscle contraction may press the urethra against the pubic symphysis, creating a mechanical pressure rise [30]. Pelvic floor muscle contraction also supports the pelvic organs [30]. Timing might be one of the most important elements; in healthy continent women, activation of the PFM before or during physical exertion seems to be an automatic anatomic response, so it is, in essence, an unconscious contraction [63,64]. This PFM “reflex” contraction is a fast feedforward loop and might precede the bladder pressure rise by 200–240 milliseconds [65,66], something that might have been lost in SUI women. Also Bø has suggested that a well-timed, fast, and strong pelvic floor muscle contraction may prevent urethral descent during intra-abdominal pressure rise [67,68]. So pelvic floor muscle training is especially focused on adequate timing, strength improvement, and coordination of the periurethral and the pelvic floor muscles.

Appropriate treatment with PFMT should always include an assessment of pelvic floor muscle contraction and relaxation, because the effect of PFMT is dependent on whether the contractions and relaxations are performed correctly [68].

Repeated correct contractions of the pelvic floor, strengthening the pelvic floor muscles in a regular, intensive, and long-lasting training program, are essential for effective improvement through PFMT [68–70].

Extrapolation of exercise prescription guidelines suggests that pelvic floor muscle training should include short- and long-duration exercises, based on diagnostic findings, as both type I and type II muscle fibers need to be exercised with overload strategies. The frequency and the number of repetitions of exercises should be selected following assessment of the pelvic floor muscles. Daily regimes of increasing repetitions to the point of fatigue seem to be recommended (8–12 *maximal* pelvic floor muscles contractions, 1–3 seconds to 6–8 seconds hold/relax, three extra quick peak contractions superimposed on the maximal contraction, three times a day for at least 6 months [70]). A process of patient awareness of isolated contractions to fully automatic controlled function of the pelvic floor during multiple complex tasks is required [16].

It is very important to select relevant starting positions tailored to the individual patient while training. In addition, functional activities must be incorporated into the training program as soon as possible [43]. An individually tailored home exercise program manageable during daily life activity is essential [68].

Because the total urethral closing mechanism also depends on a competent intrinsic urethral sphincter (in case of incompetence, this is termed intrinsic sphincter deficiency [ISD]), there is no guarantee that improvement of timing, absolute strength, and endurance of the pelvic floor, with respect to the extrinsic part of the total urethral closing mechanism, will fully restore continence [62].

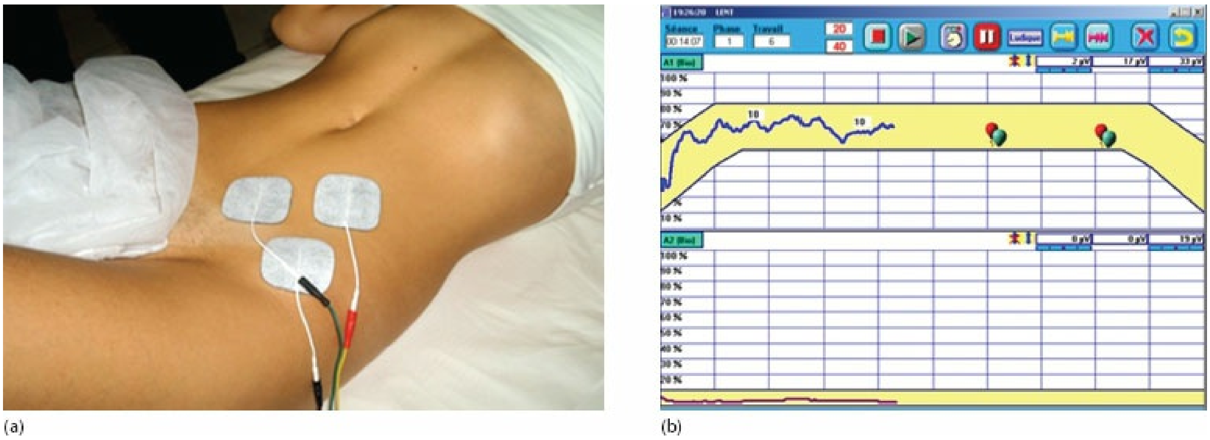
Meanwhile, there is sufficient evidence that PFMT is effective in the reduction of involuntary loss of urine in patients with stress incontinence, which is sustained for the long term [71–74].

In general, intensive training showed better results than a low intensity program [43,75,76].

Twenty-five percent of females are still dry after 5 years, while two-thirds of them indicate by follow-up that they are very satisfied with their present state and that they wish no further intervention.

Biofeedback refers to a range of audiovisual techniques whereby information regarding “hidden” physiological processes, in this case pelvic floor muscles contractions and relaxations, is displayed in a form understandable to the patient, to permit self-regulation of these events [43]. For instance, biofeedback can be used to teach a patient with SUI to selectively contract their pelvic floor muscles. A sensor or electrode is introduced into the vagina or rectum, to record the vaginal or rectal pressure or the ani electromyogram (EMG) signal of the sphincter muscle. The patient receives visual or acoustic information about the pressures measured and/or the EMG signals, enabling them to see what force is being generated by the pelvic floor muscles and whether this force has reached its maximum.

Recently, wireless biofeedback devices have been developed, introducing new technology and training program strategies (Figure 43.3). With the help of wireless biofeedback, numerous actions related to involuntary urine loss during daily activities can be mimicked, also enhancing the patient's motivation and adherence. Further studies to validate these promising innovative techniques and applications are needed. Recent research has investigated the use of extracorporeal ultrasonography to show patients with SUI whether they are producing the correct type of lift (in an inward and upward direction) of the pelvic floor during contraction [77].



(a) (b)

Figure 43.4 Electromyogram (EMG) biofeedback. (a) EMG biofeedback, here registered by surface electrodes, can be used to visualize on-screen; (b) selective pelvic floor muscle activity (blue line) together with control of any synergistic abdominal muscle activity (red line). (From Berghmans B et al., in: *Atlas of Bladder Disease*, Staskin D (Ed.), Springer, New York, 2009.)

Dietz et al. used suprapubic external ultrasonography for this purpose [78]. They concluded that this form of biofeedback takes little time (an average of 5 minutes) and is effective as well as efficient and as such is a useful strategy to teach patients to produce the right contractions.

Ultrasonography can also be used to estimate the volume (thickness) of the pelvic floor. But this type of biofeedback cannot be used to measure muscle strength [58,78]. Further research will be needed to assess methodological aspects of this type of biofeedback, such as its validity and reliability [58].

Biofeedback is not a treatment on its own. It is an adjunct to pelvic floor muscle training.

Biofeedback is based on operant conditioning and a cognitive learning process. An incontinence patient can be taught, with the aid of biofeedback, to be selective in the use of the pelvic floor muscles (Figure 43.4).

Usually, at the onset of therapy with biofeedback, the motor unit activity (EMG) or the intravaginal/anal pressure of the pelvic floor muscles (manometry) at rest, during a maximal pelvic floor muscles contraction (Pmax) and relaxation after Pmax are measured.

In an RCT comparing a group using PFMT with biofeedback and a group without biofeedback, Berghmans et al. [55] demonstrated quicker progress in the first group. In the long term, for the treatment of stress incontinence, biofeedback in combination with PFMT seems equally effective as only PFMT [55,79–81].

Nevertheless, in patients with urinary incontinence who have insufficient or no awareness of the pelvic floor muscles and therefore are not able to voluntary contract or relax their pelvic floor muscles or have very poor quality (intensity) of contraction at initial assessment, biofeedback is suggested to be an important strategy to quicken up and restore this awareness [43,55,67,82]. However, further large, high-quality RCTs are required in order to proof this hypothesis [43,55].

Electrical stimulation is generally provided by clinic-based electrical equipment (i.e., those that need to be plugged into a wall socket) or portable battery-powered stimulators (Figure 43.5).

Although relevant studies poorly report the biological rationale underpinning the application of electrical stimulation for the treatment of SUI [43], the aim of electrical stimulation in this setting appears to be to improve the function of the pelvic floor muscles, while for patients with urgency incontinence, the objective seems to be to inhibit DO.

For stress incontinence electrical stimulation is focused on the restoration of the reflex activity through stimulation of the fibers of the pudendal nerve with the purpose to create a contraction of the pelvic floor muscles [83]. Electrical stimulation is suggested to lead to a motor response by patients for whom a voluntary contraction is not possible as a result of an insufficient pelvic floor, on the condition that the nerve is (partly) intact [84].

Although electrical stimulation appears to be better than placebo, its effect in stress incontinence has not been sufficiently demonstrated due to inconsistency in study protocols [43,72].

There are many differences in potential clinical application that have not yet been investigated. For example, some clinicians suggest that “active” electrical stimulation (i.e., the patient voluntarily contracts the pelvic floor muscles during stimulation) is better than “passive” electrical stimulation, but the effect of these two approaches has not yet been evaluated [43,72]. Equally, it may be that some populations or subgroups of patients benefit from electrical stimulation more than others.

Figure 43.5 Wireless biofeedback equipment for urinary continence: POD universal, which is an external device for registration wireless connected medical machine. (Courtesy of Vivaltis, Montpellier, France.)

Although to date there is still insufficient evidence, in clinical practice, we suggest using electrical stimulation in patients with stress incontinence, who—during assessment—were not capable of performing an active voluntary contraction of the pelvic floor muscles. The following parameters may be used as a starting point:

- *Pulse shape*: bipolar rectangular square wave
- *Frequency*: 50 Hz
- *Pulse duration*: 200 microseconds
- *Duty circle*: ratio 1:2
- *Intensity of current*: maximal tolerance
- Two times/week office bound, two times/day at home, until voluntary contraction by the patient himself or herself is possible and adequate

Magnetic stimulation has been developed for stimulating both central and peripheral nervous systems noninvasively [85]. Magnetic stimulation has been applied to pelvic floor therapy and the treatment of urinary incontinence and was reported in treatment of this condition for the first time in 1999 by Galloway et al. [86]. Contrary to electrical stimulation, extracorporeal magnetic innervation (ExMI) aims to stimulate the pelvic floor muscles and sacral roots without insertion of an anal or vaginal probe [87,88]. For treatment, the patient is positioned in a chair. Within the chair's seat is a magnetic field generator (therapy head) that is powered and controlled by an external power unit. Conventional stimulators deliver, at frequencies of 10–50 Hz, repetitive pulses of current between less than 100 microseconds [66] and 275 microseconds [65] in duration. Size and strength of the magnetic field are determined by adjusting this amplitude by the physiotherapist [86]. A concentrated steep gradient magnetic field is directed vertically through the seat of the chair. When seated, the patient's perineum is centered in the middle of the seat, which places the pelvic floor muscles and sphincters directly on the primary axis of the pulsing magnetic field. Because of this, all tissues of the perineum can be penetrated by the magnetic field. Galloway indicated that no electricity, but only magnetic flux, enters the patient's body from the device [86]. Goldberg indicated that, in contrast to electrical current, the conduction of magnetic energy is unaffected by tissue impedance, creating a major advantage in its clinical application compared to electrical stimulation. In that way, structures, such as sacral roots or pudendal nerves, might therefore be magnetically stimulated without patient's discomfort or inconvenience of probe insertion for electrical stimulation [87].

Therefore, advantages of ExMI seem to be that it is performed through full clothing, entailing no probes, skin preparation, or physical or electrical contact with the skin surface. On the other hand, the need for repeated office-based treatment sessions represents an inherent disadvantage. In contrast to electrical stimulation units, this kind of technology lacks portability, and, because both the depth and width of magnetic field penetration is proportional to coil diameter, the present technology according to Goldberg is best suited for stimulation of a field, rather than a narrowly focused target such as the sacral roots or the pudendal nerve [87].

Magnetic stimulation of the sacral nerve roots and pelvic floor is suggested to be effective for SUI [87,88] although the mechanism of action on the continence mechanism is not fully understood [88]. Some authors suggested that in SUI it stimulates pelvic floor musculature causing external sphincter contraction [89], acting as a kind of a passive pelvic floor muscle exercise [90], and an increase of maximal urethral closing pressure [91]. Stimulation of sympathetic fibers maintaining smooth muscle tone within the intrinsic urethral sphincter seems to be involved in this mechanism of action [92,93]. Previous studies suggested a stimulation frequency of 50 Hz to be the most effective for urethral closure [86].

There is only limited evidence of the effect of magnetic stimulation treatment in women with SUI. There was considerable variation in diagnostic groups, the regimen, protocols, intensity, and duration of treatment. Sample sizes were small, and outcomes were contradictory. Only short-term results were available. At the moment, there is not enough evidence of the efficacy of magnetic stimulation to recommend this therapy in women with SUI [86].

In women with stress incontinence, weighted vaginal cones in combination with PFMT are sometimes used [72,94,95]. All cones are identical in size, but have increasing weight. The idea is that the stronger the pelvic floor muscles grow, the higher weight of a cone can be held in place and therefore continue to stimulate the pelvic floor muscles to hold the cone inside the vagina. A review by Herbison et al. provided some evidence that weighted vaginal cones are better than no active treatment but on the other hand add no benefit to a pelvic floor muscle training program alone [43,95]. Vaginal cones may add benefit to a training protocol if subjects are asked to contract around the cone and simultaneously try to pull it out in lying or standing position while performing their pelvic floor muscle exercises in the way described earlier [96].

Because of the lack of evidence about their efficacy and doubts regarding the theoretical basis of this treatment modality, Bo et al. stated that widespread use is not recommended [94].

On the other hand, in the latest update of their Cochrane Collaboration Review, Herbison and Dean suggest that, based on the sparse evidence that weighted vaginal cones are better than no active treatment, these could be offered as one treatment option, if women find them acceptable [97].

Guidelines for Stress Urinary Incontinence

In the KNGF guidelines for stress incontinence, the following problem areas are differentiated [16]:

- Stress incontinence with a dysfunction of the pelvic floor
  - With awareness of the pelvic floor.
  - Without awareness of the pelvic floor.
  - The function of the pelvic floor is compromised by dysfunctions in the respiratory or the locomotive tract.
- Stress incontinence without a dysfunction of the pelvic floor
- Stress incontinence (with or without a dysfunction of the pelvic floor) in combination with general factors that inhibit or delay improvement or recovery

Stress Incontinence with a Dysfunction of the Pelvic Floor

The primary aim of treatment is to obtain a good awareness of the pelvic floor muscles. During the treatment, the following techniques are used: digital palpation either by the patient herself or by the physiotherapist and electrical stimulation and/or biofeedback in combination with pelvic floor muscles training. If the patient is aware of contraction and relaxation of the pelvic floor muscles, the therapy continues with the use of PFMT only. If a pelvic floor dysfunction coexists with dysfunctions of the respiration or the locomotive tract or with inadequate toilet behavior, these issues need to be addressed additionally. The ultimate aim of the treatment is a complete restoration of the functionality of the pelvic floor.

Stress Incontinence without a Dysfunction of the Pelvic Floor

Without a dysfunction of the pelvic floor, an ISD is likely. Here, pelvic floor training can only provide some degree of compensation at the most. A complete cure is merely impossible.

Stress Incontinence in Combination with General Factors That Inhibit or Delay Improvement or Recovery

In this case, physiotherapy will aim at the reduction of these negative general factors. Avoiding specific situations by the patient, impaired social participation, and feelings of shame related to involuntary urine loss can be reduced by the physiotherapist using relevant information, education, counselling, and care.

In Table 43.4, an algorithm of the process of therapy for stress incontinence in women is given.

Table 43.4 Algorithm of Process of Therapy for Stress Incontinence in Women

- Process of therapy
  - Therapeutic training/management for distinguished problem areas
    - GSI + dysfunction pelvic floor + *no* awareness of pelvic floor:
      - Digital palpation by patient and/or physiotherapist
      - Electrostimulation (intravaginal/extravaginal) + PFMT
      - Biofeedback + PFMT
  - Objective: restoration of awareness of the pelvic floor
    - If awareness restored → see 1b
    - Unsatisfactory results → back to referring physician
    - GSI + dysfunction pelvic floor + awareness of the pelvic floor:
      - PFMT + home exercises; isolated contractions of the pelvic floor → with awareness of pelvic floor, single tasks → double tasks → multiple tasks → automatic controlled tasks; optional: vaginal cones
  - Objective: total recovery (of the functionality of the pelvic floor)
    - Unsatisfactory results → back to referring physician
    - GSI + dysfunction pelvic floor + function pelvic floor malinfluenced by disorders of tractus respiratorius or other parts such as tractus motorius, toilet regimen, toilet behavior
      - PFMT + home exercises
      - Exercises to achieve adequate respiration, postural exercises
    - Relaxation exercises, lift instruction
  - Objective: reduction or elimination of malinfluence disorders, improvement functionality of the pelvic floor
    - Unsatisfactory results → back to referring physician
    - GSI + *no* dysfunction of the pelvic floor
    - PFMT + home exercises; optional: vaginal cones
  - Objective: compensation. Expectation: total recovery not likely

Unsatisfactory results → back to referring physician
GSI + general obstructing factors
Objective: maximal possible reduction of these negative factors
Unsatisfactory results → back to referring physician
Evaluation
Treatment results (changes in), patient's health status, course of action of physiotherapist
Concluding treatment period and reporting to referring physician

Detrusor Overactivity

In this condition, the patient has no or insufficient control over involuntary detrusor contractions, which can result in involuntary urine loss [97]. Physiotherapy for DO consists of patient information and education, toilet training, bladder (re-)training (BlT) or behavioral therapy, PFMT with or without biofeedback, electrical stimulation, and magnetic stimulation. All physiotherapeutic modalities can be used alone or in combination with each other or in combination with medication.

Patient information and education is provided about the lower urinary tract function, the function of the pelvic floor, and the way to contract and relax the pelvic floor.

The goal of toilet training is to change inadequate toilet behavior and regimens, i.e., aiming at the aspects of the micturition process itself.

BlT aims to restore normal bladder function using patient education together with a scheduled voiding regimen in order to increase the time interval between two consecutive voidings [98,99]. It consists of four components. The first is an educational program that addresses lower urinary tract function. The next component involves training to inhibit the sensation of urgency and to postpone voiding. The third is to urinate according to a timetable in patients with an interval less than 2 hours between two consecutive micturitions in order to reach an interval of at least 3 hours between two consecutive voidings and to reach larger voided volumes. The fourth step is reinforcement of patient motivation by the physiotherapist.

Especially in those patients whose functional capacity of the bladder is too small, a BlT program can provide normalization of bladder capacity. So far, the exact working mechanism of BlT remains unclear [43,99,100]. Improvement of cortical inhibition over involuntary detrusor contractions [101], central modulation of afferent sensory impulses or cortical facilitation over urethral closure during bladder filling [102], and behavioral changes leading to an increase of "reserve capacity" of the lower urinary tract system [103] have been proposed.

The efficacy of bladder training in women with DO varies from 12% to 90% [43]. From the few trials available, the ICI concluded that there is scant level 1 evidence that BlT may be an effective treatment for women with UUI and MUI (level of evidence: 1). If there is no reduction in incontinent episodes after 3 weeks of bladder training, the ICI recommends reevaluation and the consideration of other treatment options [43].

Specific PFMT *probably* facilitates and restores the detrusor inhibition reflex (DIR) by selective contraction of the pelvic floor muscles. PFMT consists of PFME and general or specific relaxation exercises. Different from the mechanism in stress incontinence, in patients with DO, selective contractions of the pelvic floor muscles during therapy are focused on the inhibition of involuntary detrusor contractions (reflex inhibition) [104].

In many patients with DO, there is concurrent high pelvic floor muscle tone [105]. The level of activation is so high that selective contraction of the pelvic floor muscles in order to achieve reciprocal inhibition of the bladder is very difficult or not possible [106]. Teaching selective contraction and relaxation of the pelvic floor muscles is then an important first step. Once this is achieved, selective contraction of the pelvic floor muscles focuses on facilitation of the DIR. After testing a patient's ability to hold contractions for at least 20 seconds by digital palpation by the physiotherapist, patients are instructed to do so, followed by a relaxation period of 10 seconds. A more functional training program (pelvic floor exercises during daily living activities) completes the exercise program.

Combinations of BlT and PFMT are also used in patients with DO. In the study by Berghmans et al., this kind of program was called lower urinary tract exercises [84].

Similar to that seen in patients with stress incontinence, with DO, and with insufficient or no awareness of the pelvic floor, biofeedback can be used to learn to control muscle functions such as reduction of an increased muscle activity or a better timing and coordination of contraction or relaxation

[55].

Wyman et al. suggested that a combination of biofeedback, PFMT, and bladder training was more effective immediately after the therapy than a separate application of each treatment modality [103].

In patients with DO, electrical stimulation theoretically stimulates the DIR and pacifies the micturition reflex, resulting in a decrease of overactive bladder dysfunction [83].

Electrical stimulation aims to inhibit involuntary detrusor contractions through selective stimulation of afferent and efferent nerve fibers in the pelvic floor. This activity results in contraction of the para- and periurethral musculature either directly or via spinal reflexes [84].

Although sometimes external electrodes have been used, electrical stimulation is mostly applied vaginally or anally through plug mounted electrodes [25,43]. A patient is instructed to use the maximal tolerable level during stimulation. In relevant studies, the following treatment characteristics were used: frequency modulation of 0.1 second trains of rectangular biphasic 200 microseconds [84,107] or 400 microseconds [108] long pulses that varied stochastically between 4 and 10 Hz [84] or with a fixed frequency of 10 Hz [107,108]. Acute electrical stimulation can be applied (mostly 1–2 times a week during 20 minutes) or chronic electrical stimulation (daily at home, e.g., every 6 hours 20 minutes).

Besides office-based electrical stimulation, portable electrical stimulation devices for self-care by patients themselves at home have been developed [84] (Figure 43.6).

Magnetic stimulation of the sacral nerve roots and pelvic floor is suggested to be an effective treatment modality for urgency urinary incontinence [87,88]. The mechanism of action to improve or restore urgency urinary incontinence is still not fully clear [88]. Using low-frequency stimulation (e.g., 10 Hz) [91] for the treatment of urgency urinary incontinence, magnetic stimulation might suppress DO through at least two autonomic effects: by activation of pudendal nerve afferents blocking parasympathetic detrusor motor fibers at the spinal reflex arc or by activation of inhibitory hypogastric sympathetic neurons or by a combination of both mechanisms [93]. Modulation of pudendal nerve afferent branches stimulating an inhibitory spinal reflex at the S3 nerve root is also suggested to play a role in this mechanism of action [93].

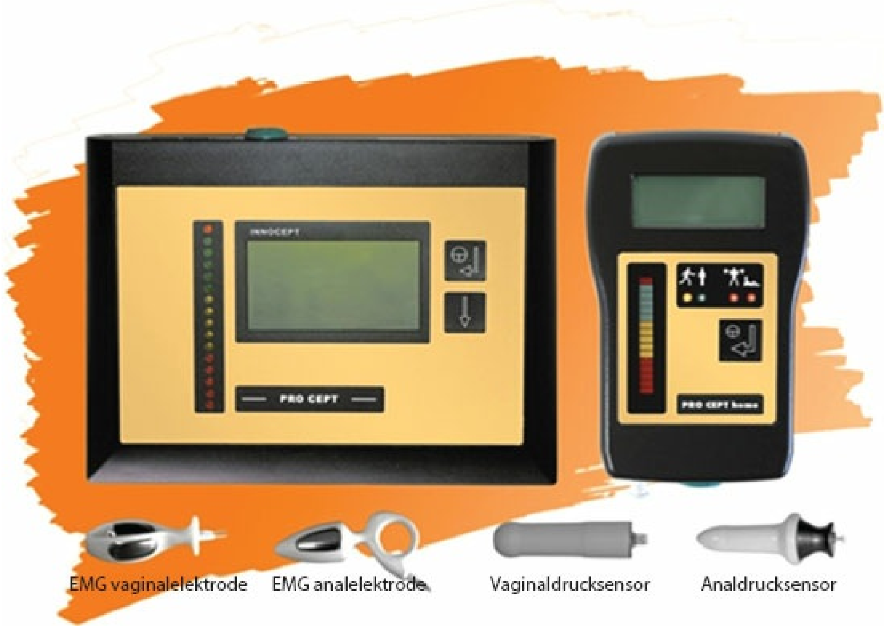


Figure 43.6 Office-bound and home devices for electrical stimulation. (By permission of Biobedded MgbH, Gladbeck, Germany.)

Only sparse evidence of the effect of magnetic stimulation vs. no treatment, placebo or control treatment in women with urgency urinary incontinence, is available. So far, only short-term results have been reported. At the moment, there is not enough evidence for the efficacy of magnetic stimulation in women with urgency urinary incontinence to recommend this therapy.

In summary, with regard to the evidence for the different treatment modalities for DO, the following conclusions can be made: the efficacy of bladder training in women with DO is still pending and varies from 12% to 90% [43]. Despite a positive trend in several studies [84,108] with reported success rates around 45%–50%, today there is still insufficient evidence for the efficacy of PFMT programs with or without biofeedback in patients with DO [25,43,84]. Three high-quality RCTs show that acute and chronic electrical stimulations, office and home based, are effective in 70% of all cases [84,107,108]. This treatment modality may be the treatment of first choice in patients with DO [43,84,107,108].

Mixed Incontinence

The physiotherapeutic diagnostic and therapeutic process focuses on the predominant symptom of the mixed urinary incontinence: stress vs. urgency. If the symptoms of urgency/frequency appear to be dominant, mostly the aim will be to reduce and improve these factors. In these cases, if the physiotherapist erroneously starts with addressing the stress component, this can provide a negative influence on the urgency component, potentially introducing more severe urgency/frequency. Reduction or improvement of the latter symptoms will provide a solid base for the subsequent treatment of the stress component. The choice of therapy modalities depends on the nature, extent, and severity of the health problem and is based on the analysis and evaluation of the physiotherapeutic diagnostic process.

PATIENT EDUCATION IN PHYSIOTHERAPY PRACTICE

In order to achieve a permanent positive result from physiotherapy, patients have to incorporate the newly acquired abilities into daily life. The physiotherapist is the most important mentor in this behavioral modification. Patient education is a very important aspect of this kind of care, and a professional attitude toward providing patient education is required. Van der Burgt and Verhulst developed a model for allied health professions as an instrumental tool for patient education [109]. This model is a combination of the ASE model and the so-called steps model of Hoenen et al., developed for individual patient education [110]. In the ASE model, the premise is that the interplay between *a*ttitude, *s*ocial influence, and own *e*fficacy determines the willingness to modify behavior (Figure 43.7).

In the model of van der Burgt and Verhulst, a number of stages are distinguished, such as thinking, feeling, and doing. In patients with urinary incontinence, this model can be transformed into an exchange of information and explanation (thinking); in awareness and feeling of the pelvic floor, posture, and movement (feeling); and in training of the pelvic floor and promotion of short- and long-term compliance (doing). The standardized patient education model of van der Burgt and Verhulst can be seen as an example of how to facilitate best practice and thus can provide physiotherapists with a framework upon which to base patient education in urinary incontinence.

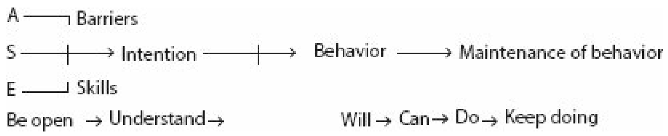

Figure 43.7 Parallels between the ASE model and the Steps model. (From van der Burgt M and Verhulst F, Gedragsmodellen, in: Van der Burgt M and Verhulst F, eds., *Doen en blijven doen*, Bohn Stafleu Van Loghum, Houten, the Netherlands, p. 31, 1996.)

CONCLUSION

Pelvic physiotherapy often appears to be effective in the treatment of incontinence.

For this reason, physiotherapy is a valuable treatment option in the management of patients with urinary incontinence.

44 Pessaries and Devices: Nonsurgical Treatment of Pelvic Organ Prolapse and Stress Urinary Incontinence

Catherine S. Bradley

INTRODUCTION

Pessaries, or devices placed in the vagina to support the uterus or vaginal walls, have been used for thousands of years to treat pelvic organ prolapse (POP). Hippocrates documented the use of pomegranates soaked in vinegar as vaginal pessaries, and ring pessaries made of wood, cork, silver, and gold were described in the early 1700s [1,2]. In the nineteenth century, the development of pessaries made out of vulcanized rubber allowed safer long-term use [2]. Pessaries remained the treatment of choice for POP through the early 1900s when over 100 types of pessaries were available, but their use declined in the following decades as developments in aseptic techniques and anesthesia made surgical correction more feasible.

Pessaries are currently considered the primary nonsurgical treatment option for POP and an important treatment option for stress urinary incontinence (SUI). However, opinions on pessary use, pessary training, and pessary management continue to vary widely among clinicians. Several surveys of gynecologists and urogynecologists in the United States and United Kingdom suggest most (77%–87%) offer pessary treatment for prolapse, but a significant minority are not involved in pessary care or offer pessaries only to women who are not surgical candidates [3–5]. While the majority of gynecologists surveyed in one U.S. study offered pessary fitting for POP, most reported they received minimal training in pessary use and few believed pessaries were an effective treatment for SUI [6].

Many experts now recommend pessaries as a long-term treatment option for any woman with POP and SUI seeking nonsurgical therapy, not just for women for whom surgery is not an option [7]. However, evidence on the effectiveness of pessaries and other mechanical devices for the treatment of POP and SUI remains limited.

PESSARIES FOR PELVIC ORGAN PROLAPSE

Pessaries used for treating POP can be loosely grouped into supportive and space-occupying pessaries. Supportive pessaries (Figure 44.1) are held in place by levator muscle tone, while space-occupying pessaries (Figure 44.2) keep prolapse reduced by filling the vagina. Most pessaries today are made from medical-grade silicone, which is nonallergenic, nontoxic, and latex-free. This material does not absorb odors, and it can be sterilized and lasts for several years.

Effectiveness of Treatment

Prospective research on the effectiveness of pessaries for POP treatment is sparse. In fact, experts have identified an “urgent need” for randomized controlled trials focusing on the effectiveness of pessaries as well as on aspects of pessary management [8]. In 2007, Cundiff et al. [9] published the only randomized trial focusing on pessary therapy for POP. This multicenter, randomized crossover trial compared outcomes of women with symptomatic POP treated with two common types of pessaries. Women were randomized to initial treatment with a ring with support pessary or with a Gellhorn pessary. After 3 months of treatment, participants were fitted and treated with the other type of pessary. The primary outcome was change in prolapse symptoms, assessed using validated questionnaires. The percentage of participants who successfully fit with at least one pessary is 92%, and 60% continued the pessary therapy for 3 months (there were no differences seen between pessary types). Using a strict criterion for defining clinically significant improvement in quality of life scores, both pessaries were found to be equally effective in decreasing POP-related symptom bother as well as bother from obstructive and irritative urinary and colorectal symptoms [9].

Three short-term, prospective cohort studies of urogynecology patients (n = 80–203, follow-up from

4–12 months) also demonstrated significant improvements in pelvic floor symptoms when POP was treated with a pessary [10–12]. About 75% of patients were successfully fit with a pessary, and 43%–56% continued use through 4–12 months follow-up [10,11,13,14]. In one study, prolapse symptom improvement (assessed using a validated questionnaire) best predicted pessary continuation [11]. All three studies found overall improved prolapse and urinary symptoms after pessary treatment. Clemons et al. [12] found women with baseline urinary symptoms (stress incontinence, urge incontinence, and voiding difficulty) had moderate improvement (in 45%, 46%, and 53%, respectively). However, among women without urinary symptoms at baseline, 21% developed new stress incontinence symptoms, which was associated with treatment dissatisfaction.

Long-term pessary treatment outcomes were studied in a 5-year, prospective observational study of patients choosing pessary treatment for POP [15]. Of 246 patients who chose pessary treatment, 187 retained the pessary at the 4 weeks follow-up visit and were entered into follow-up. After 5 years, 53 (28.3% of the entire cohort or 35.1% of the 151 who completed 5-year follow-up) were considered treatment successes due to reduced prolapse symptoms and patient desire to continue pessary use.

Finally, two recent observational studies provide some information about treatment outcomes in patients choosing pessary treatment compared to surgery. Abdool et al. [16] performed a prospective, observational study of 359 women who selected pessary treatment and 195 women who selected surgery for POP. The majority of pessary users wore ring pessaries (83%), and 95% of the prolapse surgeries were vaginal-approach native tissue repairs. Women who selected pessary treatment were on average older (68 vs. 60 years). At 1-year follow-up, both groups had significant improvements in prolapse, urinary, bowel, and sexual symptoms. The extent of symptom improvement was similar in the pessary and surgery groups when controlled for age. However, the study had significant loss to follow-up (32% of the pessary group and 45% of the surgery group). This loss to follow-up and the observational study design limit the impact of these results.

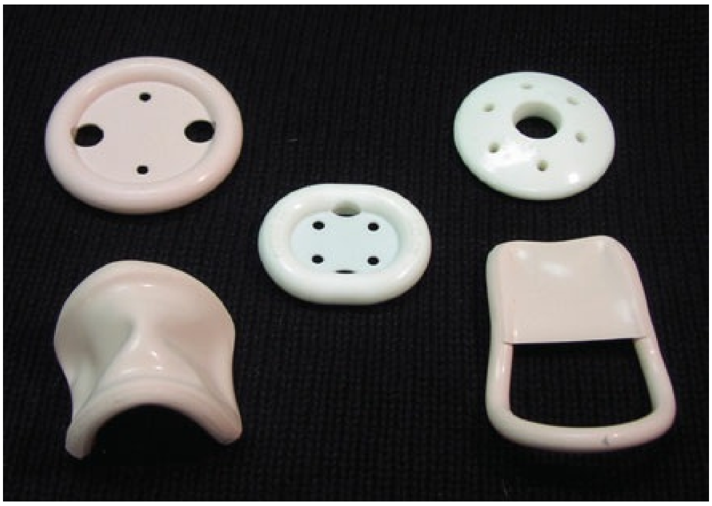

Figure 44.1 Support pessaries used to treat pelvic organ prolapse. *Top row*: (left) ring with support (Courtesy of Milex, Inc., Chicago, IL.); (right) Shaatz (Courtesy of Mentor Corporation, Santa Barbara, CA.). *Middle row*: oval with support (Courtesy of Mentor Corporation, Santa Barbara, CA.). *Bottom row*: (left) Gehrung (Courtesy of Milex, Inc., Chicago, IL.); (right) Hodge (Courtesy of Milex, Inc., Chicago, IL).

In a smaller but well-designed prospective study, Mamik et al. [17] compared short-term (3 month) treatment outcomes in women choosing surgery or pessary treatment for POP, including goal attainment, patient global impression of improvement, body image, and symptom change. Both patient groups had similar characteristics at baseline, and both treatment groups improved 3 months after treatment. In contrast to the study by Abdool et al. [16], the surgery treatment group had higher goal attainment, higher global impression of improvement, and better symptom improvement.

In summary, research published to date suggests that pessary therapy for POP will improve or resolve most prolapse symptoms as well as many bladder, defecatory, and sexual symptoms. The development of new stress incontinence occurs in a minority of patients, but it is associated with pessary discontinuation. Most women interested in pessary treatment can be successfully fitted with a pessary, and 40%–60% will continue its use for greater than 6–12 months. More studies are needed to compare outcomes after pessary treatment versus surgery before conclusions can be reached regarding comparative effectiveness.

Pessary Fitting

Rates of successful pessary fitting in the literature range from 41% to 92%, with variable definitions used for success [9,10,14,18,19]. Often, more than one visit and the use of two or more pessaries are required for fitting. Among 1216 patients with POP and UI referred to a pessary clinic, Hanson et al. [19] initially fitted 1043 (86%) with a pessary, but only 744 (62%) continued to wear the pessaries for greater than 1 month. Half of the patients required two or more visits for fitting and a median of two pessaries was tried. Clemons et al. [14] successfully fitted 73% of patients with POP with a pessary, defined as a successful fit and planned continued use of the pessary after a 1 week follow-up visit. Thirty percent of patients required two visits and on average two pessaries were tried per visit to achieve a successful fit.

Patient characteristics that predict a successful pessary fitting are inconsistent across studies [10,14,18–20]. For example, conflicting results have been reported for age and POP stage in predicting pessary fitting success [14,20]. The type of support defect (e.g., anterior, posterior or apical) is also not consistently associated with fitting failure. In several studies, prior hysterectomy and prior reconstructive surgery were more common in those with pessary fitting failure [10,18,19]. Possible anatomic predictors include a wide introitus (>4 fingerbreadths), short vaginal length (<7 cm), and larger genital-hiatus-to-vaginal-length ratio [14,20]. Among postmenopausal women, use of vaginal estrogen therapy may increase fitting success rates [19].

Pessary types used for POP vary among published reports. Many pessary providers report tailoring their choice of pessary to specific support defects [3], but this practice is based on limited evidence. Conventional wisdom states that support pessaries will be more successful in women with milder degrees of POP, while space-occupying pessaries may be required in women with advanced POP and in those with a wide genital hiatus or a weak perineal body [21]. In support of this assertion, one study found only 36% of women with Stage IV prolapse were able to be fit with a support pessary, compared to 80% of women with Stages II and III prolapse ($p < 0.001$) [14]. However, in the PESSRI clinical trial, all women were treated sequentially with both ring and Gellhorn pessaries, and fitting success rates were high (92%) and did not differ by pessary type [9].

Many published protocols use the ring or ring with support pessary as a first choice pessary in all patients because of its ease of use and reserve other pessary types (most often Gellhorn, donut, or cube pessaries) for women unable to retain or to be comfortably fitted with a ring [10,14,22,23]. In fact, 64%–70% of POP patients can be fit successfully with a size 3, 4, or 5 ring pessary [14,22].

Iowa Pessary Protocol

Given the few published studies on pessary treatment, the literature cannot guide clinicians in choosing pessary management strategies. Therefore, much of clinical pessary practice is based on clinical experience and expert opinion. Here, we present the pessary protocol used at the University of Iowa Urogynecology Clinic.

Prior to fitting a pessary, we treat most women that demonstrate vaginal atrophy for 6 weeks with vaginal estrogen therapy, as this may increase the likelihood of a successful pessary fitting [19]. Similar to other reported protocols [10,14,22], we begin by trying to fit a ring or ring with support pessary as these are easy for providers to fit and for patients to self-manage. If unable to successfully fit a ring pessary, we next try a Gellhorn pessary. Our experience mirrors reports in the literature that >90% of women with POP can be fit with one of these two pessary types [14]. If unable to fit either a ring or Gellhorn pessary, other types (commonly a donut or cube) are tried.

An appropriately fitting pessary should fill the vagina, but allow the clinician’s finger to easily sweep between the pessary and the vaginal wall. After finding a pessary with a good fit, we instruct women to do vigorous activity in the clinic area (such as brisk walking and straining) to ensure that the pessary is retained in the vagina and is comfortable. We also ask that women attempt to void with the pessary in place before leaving the office. In postmenopausal patients without contraindications to hormonal therapy, low-dose vaginal estrogen is often prescribed. In most cases, patients are scheduled for an initial follow-up appointment within 2 weeks. Women fitted with a cube pessary are asked to return sooner (within 1 week) because of an increased risk of vaginal erosions [22], which in our experience may occur rapidly.

At each subsequent pessary appointment, patients are first examined with the pessary in place to ensure correct fit and placement in the vagina. The pessary is then removed and washed. The vagina is examined for signs of excessive discharge, irritation, or erosions. Careful inspection of all vaginal surfaces is essential to identify erosions. We recommend turning the speculum 90° to visualize the anterior and posterior surfaces carefully. After an initial 2-week and 3-month check, we examine women who manage their own pessary yearly.

In contrast to reports from some centers [14,22], we find the majority of women can be instructed to remove and replace their pessaries at home. We recommend women remove the pessary once or twice weekly, leave it out overnight, and then reinsert it in the morning. When removed, the pessary is simply washed with warm water. Women rarely encounter excessive or malodorous vaginal discharge using this approach. If women are unable or unwilling to remove the pessary at home, they are seen at regular intervals in the office for pessary removal and examination. In these patients, we gradually increase the office visit interval after the initial follow-up visit to a maximum interval of 3 months. Women who develop increasing vaginal discharge or erosions over shorter intervals will need more frequent follow-up.

Visiting nurses can be an invaluable resource for women unable to care for the pessary on their own. They are often able to visit the woman at home, remove the pessary in the evening, and return in the morning to replace it. Excessive or foul-smelling discharge, increased discomfort, or vaginal bleeding signals a need to arrange medical follow-up.

PESSARIES AND DEVICES FOR STRESS URINARY INCONTINENCE

Supportive pessaries are also used for treating SUI. Pessaries used to treat incontinence frequently have a knob that is placed under the urethra (Figure 44.3). Some of the most commonly used incontinence pessaries include the incontinence dish (with or without support) and the incontinence ring with knob (with or without support) (inset, Figure 44.3), but other types (e.g., Hodge with knob) are also available. Clinical protocols for fitting and following patients with incontinence pessaries are similar to those used in patients who use pessaries for POP (described earlier). In addition to pessaries, other vaginal and urethral devices may be used to treat SUI, including tampons, diaphragms, disposable vaginal devices, and urethral inserts.

Mechanism of Action

Small prospective studies of incontinence pessaries have demonstrated positive changes in urethral function and support measures using urodynamic tests and dynamic magnetic resonance imaging (MRI) [24–26]. In 12 women who underwent urodynamic studies with and without a Smith Hodge pessary, the pessary increased urethral functional length and static and dynamic urethral closure pressures and reduced urodynamic stress incontinence (USI) [24]. Flow rates did not decrease, and voided and postvoid volumes were unchanged with the pessary, suggesting that urethral obstruction did not occur. Maximal urethral closure pressures also increased in 33 women with SUI after placement of an incontinence dish, and urethral straining angles decreased [25].

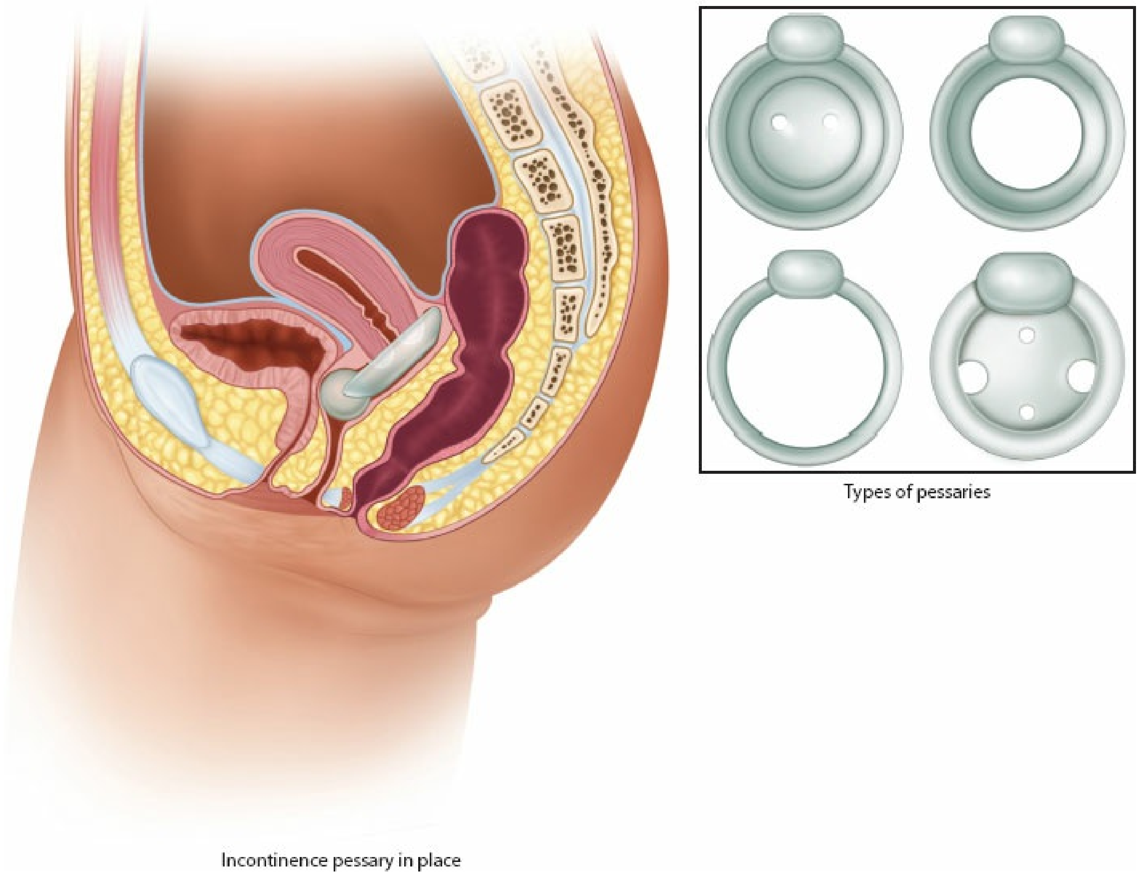

Figure 44.3 Pessary placement for the treatment of stress urinary incontinence and (inset) commonly used incontinence pessaries (clockwise from *top left*: an incontinence dish with support, an incontinence dish without support, an incontinence ring with support and knob, and an incontinence ring without support). (Figure used with permission, from Rogers RG, *N Eng J Med*, 358, 1029, 2008; Copyright © 2008 Massachusetts Medical Society. All rights reserved.)

One study used urodynamics and dynamic MRI in 15 women to assess changes associated with incontinence dish pessaries [26]. All women had USI before pessary placement, but only three had USI after placement of the dish. At urodynamics, maximal urethral closure pressures did not increase (as seen in previous studies), but functional urethral length did increase. Contrary to prior findings [24], maximal flow rates decreased and detrusor pressures increased, suggesting increased urethral resistance, although postvoid volumes were not elevated. MRI findings included greater bladder neck elevation, increased urethral length, decreased urethral funneling with cough, and smaller (more acute) posterior urethrovesical angles following pessary placement [26]. These studies together suggest pessaries may reduce SUI by stabilizing the proximal urethra and urethrovesical junction, thereby facilitating pressure transmission to the proximal urethra. Increasing urethral resistance and elevation of the bladder neck may also help restore continence.

Effectiveness

Few controlled trials have been published evaluating the use of incontinence pessaries. Nygaard et al. [27] performed a small, randomized, crossover, clinic-based study of 18 women who completed three standardized aerobics sessions, wearing either a Hodge with support pessary, a large menstrual tampon, or no device. Both devices significantly decreased urine loss (measured with a pad test) during exercise when compared to the control session. Better outcomes were seen with both devices in women who had milder urine loss [27].

The National Institutes of Health Pelvic Floor Disorders Network conducted a large, multicenter, randomized trial (the Ambulatory Treatments for Leakage Associated with Stress Incontinence [ATLAS] trial) to test mechanical devices for SUI [28]. In total, 450 participants with stress-predominant urinary incontinence were randomized to incontinence pessary, behavioral therapy with pelvic muscle training, or a combined treatment arm. After 3 months of treatment, some outcomes favored behavioral therapy over pessary therapy (bothersome SUI symptoms [33% vs. 49%, $p = 0.006$] and satisfaction [75% vs. 63%, $p = 0.03$]), but other outcomes did not differ between the groups. The combined treatment group did not have better outcomes than single therapy. At 12 months, there were no differences between the treatment groups. Using an intent-to-treat analysis at 12 months follow-up, 32% of the pessary group felt they were better or very much better, 35% reported no bothersome SUI symptoms, and 50% were satisfied with treatment. Of the original 146 women, 67 (46%) continued the use of the pessary at 12 months, and among this group, about 60% reported they were better or very much better, 60% reported no bothersome SUI symptoms, and 90% were satisfied with treatment [28].

Incontinence pessary use in practice appears quite variable. In two retrospective studies (including 100 and 190 patients), about 60% chose to undergo a pessary fitting for stress or mixed urinary incontinence, and 85%–90% were successfully fit [29,30]. Of those successfully fit with a pessary, 55%–60% continued using the pessary (median duration of follow-up 11–13 months). In contrast to these findings, in a small prospective study, only 16% of 38 women fit with an incontinence ring with support pessary chose to continue use out to 1 year [31]. In the few that continued the use, the pessary resulted in fewer leaking episodes and 9 (24%) were subjectively “dry.”

Other Stress Urinary Incontinence Devices

Fewer and typically smaller studies have tested other types of vaginal and urethral devices for treatment of SUI. The vaginal contraceptive diaphragm has been shown to decrease SUI symptoms with success rates of 40% and 75% in two small, short-term studies [32,33]. Placement of a menstrual tampon has similar moderate levels of success (57% continent during use) in treating exercise-induced incontinence [27].

In a small study (32 women), a novel bell-shaped self-positioning incontinence pessary (Uresta, EastMed, Inc., Dartmouth, Nova Scotia, Canada) was found to significantly improve urinary symptoms as well as diary-recorded leaking episodes and urinary pad weights [34]. Similar to the larger retrospective studies of traditional incontinence pessaries described earlier, 50% of women beginning the study chose to continue the use of the pessary for SUI treatment after 12 months.

Other internal vaginal devices have been developed for the treatment of SUI and have demonstrated moderate efficacy in small prospective studies. One reusable device available in Australia and Europe (Contiform International, Blacktown, New South Wales, Australia) is shaped like a large hollow tampon [35]. The device, designed to be fitted and self-managed by patients, can be reused for 30–60 days. In a small study of this device, 54% of women who completed the treatment period were dry.

Single-use, disposable vaginal devices are available for treating SUI in several countries outside the United States. The Contrelle Activgard (Codan, Kobenhavn, Denmark) is a polyurethane foam tampon.

A prospective trial of 94 women tested the Contrelle device for treatment of stress-predominant urinary incontinence, finding 48% of participants were subjectively continent and 36% improved after 5 weeks of treatment [36]. Another disposable vaginal device, consisting of a flexible resin core surrounded by a porous nylon mesh (ConTIPI Ltd., Caesarea, Israel), intends to provide urethral support similar to a tension-free suburethral sling. Used by 60 women with severe SUI, 85% had a ≥70% reduction of urine loss on daily pad weights. In the 50 women who completed the 4-week trial, 92% were subjectively continent [37].

Urethral inserts and external urethral occlusive devices function as mechanical barriers to prevent urinary leakage. These devices require highly motivated and manually dexterous patients as the devices must be removed to urinate and then replaced after each void. Studies suggest they have lower overall success rates than seen for some of the vaginal devices, partly because of higher dropout rates [38].

Urethral inserts are sterile, single-use devices placed into the urethra by the patient and held in place by an inflated balloon at the bladder neck. Such inserts are appropriate for women with no history of recurrent urinary tract infections and no serious contraindications to bacteriuria (e.g., artificial heart valves). Currently, only the FemSoft insert (Rochester Medical, Inc., Stewartville, MN) is commercially available in the United States. Multicenter studies demonstrate high rates of continence with urethral inserts in place (80%–95%) and high rates of satisfaction in women who continue use, but overall results are limited by high withdrawal rates and frequent adverse events [39,40]. While inserts remain an appropriate treatment option for many women with SUI, the need to frequently insert the device into the urethra means many patients are unwilling to try this therapy.

External urethral occlusive devices fit over the external urethral meatus and are held in place by adhesive or suction. These devices have fewer reported side effects than the urethral inserts, but reported continence rates are lower (40%–50%) [41,42]. Patient acceptability of this type of device, similar to urethral inserts, appears to be limited. Several types have been marketed in the United States in the past, but none are currently commercially available.

In summary, published studies suggest most women who are interested can be successfully fit with an incontinence pessary and about half of those women find it an acceptable and satisfactory long-term therapy for SUI. Most pessary and device studies (with the notable exception of the ALTAS trial [28]) remain limited by small sample sizes and lack of comparison groups. A 2011 Cochrane review of vaginal and urethral incontinence devices found there was still insufficient evidence to recommend any specific pessary or device or to show that mechanical devices are better than other forms of treatment for SUI [43].

ADVERSE EVENTS

Adverse events related to pessary use are uncommon and generally minor, although published data in this area are sparse. In a 5-year prospective study, 12% of pessary users experienced minor complications (including pain or discomfort, vaginal excoriation or bleeding, and constipation) [15]. Most complications occurred within the first 6 months of use. Frequent removal and care of a pessary may prevent most pessary problems [21]. Vaginal discharge, odor, and vaginal infections may also occur in pessary users, but these are infrequent reasons for discontinuing the use [22,29]. Vaginal erosions have been reported to occur in 5%–10% of women treating POP with a pessary [13,19,22], and erosions are less common in women using a pessary for SUI. In the ATLAS trial, no vaginal erosions occurred among 168 women followed to 3 months and 94 women followed to 12 months using an incontinence pessary for SUI [28]. Erosions may be more common in women with hypoestrogenic vaginal changes and in those using a cube pessary. In one case series, erosions developed in 5 of 6 women using cube pessaries, but in only 3 of 101 women using ring pessaries [22].

Vaginal erosions due to pessary use typically can be managed by removing the pessary more frequently, suspending use entirely for some period of time (e.g., 2 or more weeks), and/or with vaginal estrogen treatment. If erosions recur, a change to a different size or type of pessary may be necessary. Symptomatic vaginal discharge associated with pessary use may be treated with antibiotics and vaginal estrogen treatment or by suspending pessary use until symptoms resolve. Some clinicians routinely recommend the regular use of vaginal products for vaginal acidification or lubrication to decrease vaginal discharge or odor symptoms in pessary users, but minimal evidence exists to support or refute this practice.

More serious complications related to pessaries can also occur, such as erosion or impaction into surrounding structures or organs, but these appear to be rare and typically are seen in patients with a "neglected" pessary [44]. A 2008 literature review identified 39 cases of major complications, including 8 vesicovaginal fistulas, 5 other urological complications, 4 rectovaginal fistulas, 3 other bowel complications, and 19 impacted pessaries [44]. Sixty percent of these complications required operative management. Only 2 of the 39 occurred in women who received appropriate clinical follow-up, again supporting the importance of careful pessary management by providers and patients.

Adverse events associated with the use of disposable vaginal devices for SUI are typically mild and most often include vaginal spotting, irritation, and discomfort [36,37], and such local side effects may decrease over time as patients become more skilled at device placement. In a 4-week trial of a disposable vaginal device, 52% of patients reported adverse events (most often discomfort and spotting) in week 1 compared to 5% in week 4 of device use [37]. Vaginal infections (e.g., candidiasis), asymptomatic bacteriuria, and cystitis are infrequently reported [37].

Urethral devices, especially urethral inserts, have higher rates of adverse events than the vaginal devices. The most commonly reported complications include urinary tract infections, hematuria, and urethral and/or bladder irritation and discomfort [39,40]. These complications appear to occur most often in the first month of device use. In a long-term study of a urethral insert, symptomatic cystitis occurred in 10.5% of participants during the first month of use, but in only 2%–3% in subsequent months [40].

CONCLUSION

Pessaries and other devices are an important nonsurgical treatment option for both POP and SUI. Current research supports that most women with an interest in pessary treatment for POP or SUI can be successfully fit with a pessary, and about 50% of women who are successfully fit will continue pessary use for a year or longer. Urethral inserts and occlusive devices are also effective, but their use is limited because of more frequent adverse effects and the intensive patient effort required for use. Careful pessary and device management and follow-up is essential to minimize side effects and avoid complications. Additional clinical trials comparing pessary or device treatment with other nonsurgical and surgical treatments and long-term studies of both effectiveness and adverse events associated with pessaries and devices are needed.

45 Catheters, Pads, and Pants

Lynette E. Franklin

INTRODUCTION

History

The history of catheterization to empty the bladder dates back to approximately 1000 BC. Records from India attest to the use of tubular objects made from iron, gold, silver, and wood and lubricated with liquid butter to drain the bladder and manage urethral strictures. Chinese records from the 100 BC time period record use of lacquered onion leaves to provide hollow instruments to empty the bladder [1]. In China in AD 30, urinary retention was managed with lead and bronze pipes. These devices were smoother, as compared to other devices, and had a more manageable size that functioned both for men and women's needs. Catheters have also been found in Pompeii, preserved in the lava from the eruption of Vesuvius [2]. The early devices were rigid and did not provide the user with a continuous drainage system. Urinary catheterization was revolutionized with the advent of rubber technology. In the mid-nineteenth century, Auguste Nelaton produced catheters that were portable, flexible, and reusable. Eventually, this flexibility allowed for indwelling catheters that could be secured with tape, an external device, or sutures. Hence, the advent of the modern indwelling urinary catheter was realized.

Urosepsis was a common almost invariably fatal problem in the early years of catheterization. The introduction of antiseptics, beginning with Lister, followed by the use of antibiotic therapies decreased mortality associated with this therapy and provided better outcomes overall. In 1966, the Stoke Mandeville National Spinal Injuries Center introduced sterile technique for catheterization, which provided more options for people requiring catheterizations [1]. Shortly after the sterile technique introduction, Lapides pioneered the clean intermittent self-catheterization (CISC) technique after one of his patients reused a catheter that had been dropped, without resterilization, without untoward consequences to the patient's urinary tract.

Catheters for bladder care continue to change and evolve while providing patients with more options for comfort, ease, and safe usage.

CATHETERS

Goals of Catheterization

Catheterization of the bladder may be indicated for either the long or short term. The goals may be quite different in different situations. When considering the selection, one must consider the overall goal of therapy. These goals may include one or more of the following [3]:

- *Temporary emptying of the bladder*: This includes the maintenance of bladder drainage during periods of acute or sudden urinary retention such as that during or following surgical procedures.
- *Long-term emptying of the bladder*: Chronic bladder dysfunction and urinary retention such as that due to bladder underactivity or bladder outlet obstruction not amenable to treatment.
- *Intravesical instillation therapy and treatment*: Instillation of medications or solutions into the bladder to treat underlying diseases such as bladder cancer, interstitial cystitis, or infection.
- *Incontinence management*: To divert urine into a containment device to reduce skin exposure to moisture for goals of wound healing, patient/caregiver respite, and palliative care.
- *Studies*: Radiographic and urodynamic studies may require intubation of the bladder to instill filling media such as radiographic contrast agents or measure bladder pressures.
- *Monitoring*: Measurement of urine output in the acutely ill or postoperative patient.
- *Testing*: Catheterization can be utilized to obtain accurate postvoid residual urine measurement or acquire an uncontaminated urine specimen for laboratory analysis.

Urethral Catheterization

Definition

Urethral catheterization is the passage of a tube through the urethral os into the bladder to drain the bladder of urine. This process may be done on an intermittent basis or as a permanent indwelling arrangement. Intermittent catheterization may be chronic or a onetime event for an acute patient care need, for example, urinary retention or drug administration. Indwelling catheterization is the passage and anchoring of a catheter for an extended period of time. The catheter is not immediately removed but is stabilized to the skin through an anchoring device such as a leg strap [1].

Designs and Materials

Catheters have evolved over the years as new materials are developed and patient needs and demands dictate changes in the market. Choice of materials and design allows the best catheter to be employed. There is not one catheter that does all, but the variety currently available permits patients and care providers the opportunity to choose the best catheter for the specific need of the patient. However, depending on the location of practice and the macroeconomic environment, third-party payers or other external forces may at times dictate the catheter used (Table 45.1).

Table 45.1 Catheter Types

Material	Definition	Pros	Cons	Best use
Silicone elastomer–coated latex	A coating of chemically bonded silicone adhered to a latex catheter.	Reduces contact of latex to the urethra in the latex-sensitive patient Reduces incidence of insertion trauma, urethritis, and encrustation Less expensive than 100% latex	More flexible than 100% silicone but less flexible than 100% latex. Elastic coating may dissolve over time exposing patient to latex. Balloons may lose fluid filling over time as compared to 100% latex.	Short-term usage Patients with latex sensitivity
Red rubber latex	A latex catheter that is soft allowing for flexibility. Latex is a natural product that is a yellowish brown in color.	Flexible allowing for easy insertion especially for short-term usage Low cost Comfort	Latex based, contraindicated in patients with latex allergies. Becomes brittle after repeated usage. Swells with absorption of fluid thereby decreasing diameter of lumen and increasing outside diameter. Some toxicity with mucosal tissue resulting in stricture and inflammation. Prone to encrustations.	Short-term usage as in CICS For patients without allergies to latex
PVC	A firm catheter made from a plastic polymer that has had plasticizer added to soften and increase flexibility.	Becomes soft and pliable at body temperature Has wide internal diameter	Limited utility as indwelling catheters, since encrustation is common with greater than 1-week usage. Has been debated as to safety with exposure to liquid over long periods of time, i.e., may break down. Uncomfortable due to stiffness. Balloon may be made of latex.	CISC Short-term use
Hydrophilic coated catheters	A plastic polymer catheter with a coating of polyvinylpyrrolidone and salt. When exposed to water, this outer coating becomes very lubricated and slippery.	Easier insertion and withdrawal resulting in a minimization of urethral trauma Safer for allergy-prone patients as no latex is present Reduction in the amount of CAUTIs [4]	Only one-time use. May be difficult for some patients to manipulate secondary to the very slick nature of the catheter. Some packaging includes water to activate, may be difficult to break seal, or may become broken early, causing problems for patient with cleanup. Expensive.	Long-term usage for CISC
Silicone	An inert product that is clear or white in color.	Inexpensive Thin-walled tube with larger lumen Catheters more compatible with lining of the urethra Latex-free	Rigid and uncomfortable—increasing risk for bypassing and bladder spasms [5]. Balloons tend to form cuffs when deflated making removal difficult. Balloon has tendency to lose fluid filling over time requiring frequent evaluation for indwelling catheter. More lumen stability with irrigation and aspiration.	Long-term usage, patients with allergies to other products
Antimicrobial	Silver ions, bactericidal and nontoxic to humans, are used to coat the catheter on the outside, inner lumen, or both. Silver phosphate. Nitrofurazone impregnated.	Some evidence that CAUTI are reduced from 3.3% to 35.5% per year Potential reduction in the rate of asymptomatic bacteriuria with short-term use Reduces bacterial load for up to 14 days	More research needed to know full extent of CAUTI reduction. Expensive. Limited studies and benefit beyond 14 days. Limited clinical studies. May contain latex.	CISC, indwelling, or SPT

Size and Length

Catheters are sized in the standardized measurement developed by J.F.B. Charriere. This so-called

“French” scale is based on the metric system where the external circumference is measured in millimeters. This measurement referred to as either French gauge (Fg or Fr) or Charriere and is approximately equal to three times the external diameter. Thus, a 30 Fr catheter is 10 mm in diameter. In women, the size of catheter used most often is between 14 and 16 Fr. However, at times a larger diameter may be indicated. For an indwelling catheter, a retention balloon is located just proximal to the tip of the catheter; the balloon should be inflated properly to the correct volume. If under inflated, there can be distortion of the catheter tip, and over inflation can risk balloon rupture. Correct selection of catheter size is important to decrease pain and discomfort with insertion of the catheter. Generally, the smallest, softest catheter that is sufficient to fulfill the clinical indication for catheterization is used. At times, selection of a larger catheter may be necessary for a variety of indications including hematuria drainage.

Catheter lengths, for intermittent catheterization, are measured in the imperial or metric system. Long or male length is 42 cm or 16 in. This length is not, however, gender specific and in fact a longer catheter may be beneficial for obese women with large perineal skinfolds. Female or short length is 6 in. or 26 cm. Shorter pediatric length catheters are also available. The proper selection of catheter length should meet the needs of the patient and/or caregivers taking into consideration the patient’s habitus, preference, and dexterity. Generally, indwelling catheters are a standard long length of 42 cm.

Various catheter tips are available. Catheter tips differ in order to facilitate insertion and drainage of the bladder for a variety of clinical scenarios (see Figure 45.1).

Indwelling vs. Clean Intermittent Catheterization vs. Suprapubic

Patient Selection

Although health professionals may be very comfortable with the practice of long-term catheterization, the lay person may experience high degrees of anxiety when approached with this modality. Varying responses including fear, anxiety, and revulsion can be exhibited in the patient who is attempting to assimilate not only the diagnosis of the underlying urinary tract problem but also the prospect of caring for oneself with a foreign object.

General criteria to evaluate whether a woman should be managed with a chronic versus intermittent catheter should be reviewed with the patient and her caregivers if applicable. Evaluation should include but not be limited to the following:

- *Motivation*: This is the ability of the patient to review goals and incorporate a desired outcome into her treatment plan. Acceptable levels of self-involvement in continence care will differ between patients and an assessment of such will help develop the best treatment plan.
- *Dexterity*: This is the combination of the ability of the patient to properly position herself for catheterization and the ability to self-access her perineal area and the precision and ability of her upper arm extremities movement to separate and locate the urethral os either visually or by tactile sense. The degrees of dexterity will dictate independence with respect to urinary tract management. If a caregiver is willing to provide self-catheterization services, then he or she will need to have a similar skill set.
- *Bladder capacity*: The low-pressure storage capacity of the bladder should be adequate such that if intermittent catheterization is recommended, there can be a reasonable time interval between catheterizations so that urinary storage pressures are maintained in a safe range, urinary incontinence is minimized, and upper urinary tract integrity is maintained.
- *Adequate mental capacity*: The woman should have the cognitive capacity to independently care for herself, follow directions for self-care or alternatively, allow a caregiver to complete care with minimal stress to the patient and/or caregiver.
- *Health-care beliefs*: The choice of management is ultimately a decision made to effectively control the woman’s condition. Her understanding of the condition coupled with social, religious, personal, and economic beliefs and responsibilities should be considered as these may or may not lead to successful implementation of a given strategy.

Despite adequate planning and informed consent, problems with a catheterization method can arise after implementation has been enacted. These problems need to be identified and addressed in a time-efficient manner to decrease potential adverse outcomes. Such issues include [1] the following:

- *Psychological issues*: Implementation may require the assistance of a trained counselor or mental health expert to overcome fear, depression, and/or anger about the current situation.
- *Visual problems*: Although initially visualization of the urethral os may be assisted with the use of a mirror, the continual use of a mirror may be cumbersome and awkward especially when catheterizing away from home. Teaching patients to use manual location of the urethral opening in relation to the vagina can be beneficial to prevent this problem.
- *Dexterity changes*: Due to aging, illness, or other factors, anatomical or functional factors can change throughout the course of a woman's illness, altering her ability to continue in the mode of catheterization initially chosen. Under these circumstances, physical and occupational health services can help provide devices that may maintain or reestablish dexterity in otherwise difficult situations. These professionals are also experts with upper and lower limb aids to assist with adduction or abduction that may provide access to the urethral os. Also, these professionals may provide additional therapy that may be initiated to decrease other comorbidities that impede dexterity such as range of motion exercises for those individuals with arthritis.

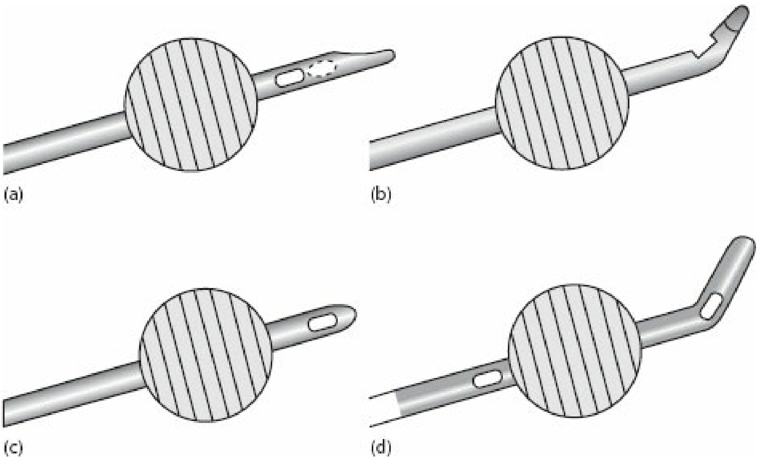

Figure 45.1 Catheter tips: (a) whistle, (b) Tiemann, (c) round, and (d) Roberts.

Technique of Clean Intermittent Self-Catheterization

The first self-catheterization will set the tone for the woman to become confident and self-sufficient in self-care. The environment should be calm, prepared, and unrushed to assist her in achieving maximum benefit from the lesson. As an adult learner, it is best that she demonstrate the catheterization as opposed to watching the health-care provider do it [6].

Many manufacturers provide written and visual material to review with patients. It is prudent to review with the patient the anatomy and physiology of the urinary tract system prior to introduction of the catheter to prevent any misconceptions of passage and potentially decrease anxiety. Written materials in the patient's native language should be given if possible to further increase knowledge acquisition.

Once the supplies are gathered, positioning the patient in a semireclining position with good lighting will aid her in seeing the urethral orifice with a mirror. Prior to attempting the initial catheterization, it is important to review her preexisting knowledge and goals and consider any limitations. These considerations will help to tailor the lesson to provide successful outcomes.

Using a touchless system with an attached drainage bag may be beneficial in the early stages of learning. This technique decreases the concerns regarding spillage of urine out of the catheter and generally decreases anxiety and embarrassment. As the woman gains mastery of CISC, her positioning may change and her ability to direct the fluid becomes easier without added appliances. Table 45.2 provides general instructions for CISC (see Figure 45.2).

Table 45.2 General Guidelines for Clean Intermittent Self-Catheterization

1. Gather supplies.
2. Wash the hands and the perineum with soap and water.

3. Separate the labia and locate the urethral os with the nondominant hand.
4. Pass the lubricated catheter into the urethra until urine passage is achieved.
5. Once the bladder is drained, slowly advance the catheter approximately 5 cm further to fully drain the bladder, and then slowly remove the catheter.

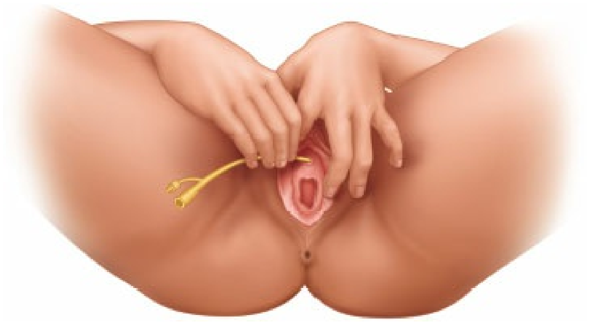

Figure 45.2 Clean intermittent self-catheterization.

Indwelling Catheters

A catheter may be placed that is retained with a fluid balloon. The catheter is placed through the urethral os into the bladder using sterile technique. The balloon is inflated with sterile water according to the manufacture's guidelines. Generally, the balloon holds between 5 and 30 cc of fluid. Saline and contrast should not be used to inflate the balloon. These fluids may crystallize in the balloon port, clogging it, and prevent balloon deflation and catheter removal. The bladder can be maintained in a decompressed state with the use of a drainage bag or may be intermittently drained with a plug. The catheter should be changed every 4–6 weeks.

Limiting unnecessary indwelling catheter usage has been identified with varying degrees of evidence from the Infectious Disease Society of America [7]. Placing and discontinuation of catheters should follow proper indications while considering the needs of the patient. The Centers for Disease Control and Prevention has outlined examples of appropriate indications for catheters including acute urinary retention or bladder outlet obstruction, accurate measurement of urine output in critically ill patients, and specific needs such as long-term diuretics, healing of open sacral and perineal wounds in incontinent patients and immobilized patients, and end-of-life care improvement [8].

Suprapubic Catheters

A suprapubic tube (SPT) is an indwelling catheter that is surgically percutaneously placed through the abdominal wall directly into the bladder. It is secured in this location using the same balloon mechanism as a urethral catheter. This type of drainage system avoids urethral catheterization. Approximately 1 month after initial placement, a well-healed epithelized tract is formed maintaining a patent opening for simplified office-based catheter changes. These tubes are indicated for patients who are unwilling or unable to manage urethral indwelling catheters or clean intermittent catheterization, for those individuals who have urethral disease precluding placement of a urethral catheter (e.g., severe urethral stricture disease), and for those who are at risk for complications such as urethral erosion and fistula formation. SPTs may be temporary, for example, in patients who have recently had pelvic surgery and maximal (when also combined with a urethral catheter) bladder decompression must be maintained temporarily postoperatively. This therapy is not optimal for the patient who is willing and able to perform CISC. As described later, indwelling tubes (urethral and suprapubic) are associated with complications that are much less likely than with CISC.

SPTs are usually placed electively in the operating room in sensate patients. Under anesthesia, a catheter is passed directly into the bladder via a stab incision through the abdomen 2–4 cm cephalad to the symphysis pubis. The catheter is exchanged in the office or in the patient's residence every 4–6 weeks. A well-epithelized tract develops through the abdomen wall into the bladder allowing for simple catheter changes. When counseling a patient about the possibility of this catheterization type, acknowledgment and discussion about altered body image are essential. Many patients will find it difficult to accept a permanent foreign body protruding from their abdomen, identifying concerns of “normal function loss,” changes in sexual practices, and leakage. Although such concerns are warranted, quality of life indicators may actually improve when patients have been converted from urethral to a suprapubic catheters especially in patients who are dependent on wheelchairs or who are sexually active [9] (see Figure 45.3).

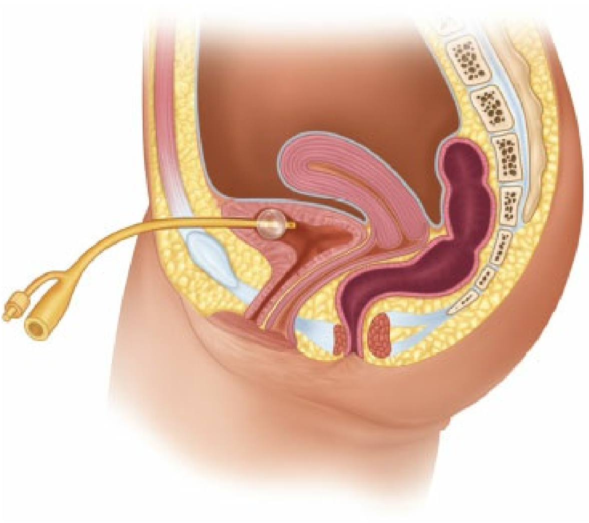

Figure 45.3 Position of suprapubic catheter.

Catheter-Associated Problems

Infection/Hematuria/Trauma

The most prevalent type of hospital-acquired infection is urinary tract infections (UTIs), with 80% of infections being associated with indwelling catheters (catheter-associated UTIs [CAUTIs]) [4]. Women are more susceptible to CAUTI as compared to men [10]. Infection is related to several potential mechanisms of entry of bacteria: insertion technique, cross-contamination with staff care, or retrograde flow from drainage bags.

UTI symptoms in patients with catheters are often atypical. Upon insertion of the catheter, bacterial biofilms will begin to develop within 24 hours. These bacterial colonies are found on the device surface, and they will not necessarily result in an infection. Patients with catheters often have bacteriuria, which is the presence of bacteria in normally sterile urine. Bacteria will be present in the bladder within 2–10 days of insertion, but not necessarily result in an infection [10]. After 30 days of an indwelling catheter, virtually all patients have bacteriuria due to colonization. This colonization of bacteria may not be eliminated with antibiotic use, and in the vast majority of cases, it is not necessary to do so. Bacteriuria or colonization is not equivalent to infection, the latter of which mandates treatment. It is important to differentiate colonization from infection. An infection is an immunological activation in response to a foreign body such as a microorganism. Colonization is a symbiotic growth of bacteria in the body that does not result in activation of the body’s immune system.

Newman [10] has outlined signs and symptoms of UTI in nursing home residents with catheters to include two of the following:

- Fever (>38°C) or chills
- New flank pain or suprapubic pain or tenderness
- Change in character of urine (smell, blood, etc.) *or* lab report of new hematuria or pyuria
- Worsening mental or functional status
- Local findings of obstruction, leakage, mucosal trauma, or hematuria

If a UTI is suspected with an indwelling catheter or in a patient who self-catheterizes, the specimen needs to be obtained from a new catheter insertion [11]. The catheter is changed and the urine is obtained from the bladder through the new tube. This prevents a sample of the catheter biofilm being collected and is more representative of the bladder flora.

Multiple other complications may result from catheter usage [12]. Long-term catheter usage may result in the formation of bladder stones. Hematuria may result from the trauma of insertion, the trauma of removal, or the trauma with sudden traction on the tube itself. Trauma from insertion or removal without deflating the balloon can cause urethra injury, tearing, or subsequent stricture. Removal of the catheter inadvertently is common among women with dementia or those prone to falls, those who strain for bowel movements, or when excessive tension is suddenly placed on the catheter [10]. Securing the catheter to the leg can aid in decreasing the movement of the catheter and friction on the perineal skin and potentially reducing bladder spasms. In addition, secure placement of the bag probably reduces intravesical trauma thus reduces gross hematuria. Devices to secure catheters are available in a variety of forms including self-adhesives, Velcro closures, latex leg straps, and abdominal belts. There has not been consensus established as to the most beneficial location for placement of the securement device, but rather to place it to provide maximum functioning for the women wearing the catheter [10]. Fistula, traumatic hypospadias, and bladder cancer are also complications associated with catheter usage.

Complications specific to suprapubic catheterization are similar to those complications listed for other types of catheters [6]. In addition, the placement of the SPT may result in bowel injury, vascular injury, and soft tissue infection. Published complications rates [13] resulting from urinary catheterization include the following:

- *Bladder stones*: approximately 1/3 in over 10 years
- *30-day complication rate*: 19%
- *Mortality rate*: 1%
- *Long-term complications including recurrent UTIs*: 1%
- *Catheter blockage*: 25%

The Joanna Briggs Institute [14] developed a best practice paper on short-term catheter removal based on a review on current research. These authors recommend for practice the following three strategies for removal of short-term indwelling urethral catheters, defined as insertion for a period from 1 to 14 days:

1. Timing of removal when appropriate should be at midnight.
2. Duration of catheterization should be as brief as possible and medically appropriate following pelvic surgery. Early catheter removal results in a reduced risk for UTI and a shorter hospital stay, but also carries with it a greater risk of subsequent short-term voiding problems.
3. Placing and removing a clamp from the tube to “retrain the bladder,” a technique known as clamping, prior to the removal of the catheter has limited degree of effectiveness in facilitating a successful voiding trial.

Leakage

Pericatheter leakage (also termed “bypassing”) should always be investigated [15]. Causes for pericatheter leakage include UTIs, stones, malignancy, bladder overactivity (“spasms”), poor drainage due to clogging, urethral erosion, and a number of other causes. A careful physical examination and history along with gentle irrigation will be able to differentiate between several of these entities. Careful assessment of the patient and the system should be conducted to evaluate for easily reversible factors such as tubing kinks and poor catheter drainage. The addition of an antimuscarinic agent may treat leakage associated with bladder spasms. Before prescribing these medications, other causes of pericatheter leakage should be considered and investigated when appropriate.

Drainage Bags

Before the advent of drainage bags, indwelling urinary catheters were drained into nonsterile open systems. Ascending bacterial infections occurred very commonly in this setting. Subsequently, closed drainage systems with nonreturn valves were developed that reduced the incidence of ascending bacteria from the bag to the person. Drainage bags range in collection volumes of 250–1000 mL. These bags can be fastened to the bed, the leg, or the abdomen. Volume selection may be changed based on the need. For example, larger systems are convenient for overnight use, and smaller leg bags may be used discreetly during the day. These can be washed and reused for several months at a time. Recommendations for bag cleaning are listed in Table 45.3. Minimal disruption of the closed system should be maintained to reduce infection risk. Strict adherence to a hand washing prior to manipulation should also be maintained.

Table 45.3 Recommendations for Bag Cleaning

1. Rinse bag with lukewarm water.
2. Vigorously agitate clean water in the collection system twice.
3. Pour a diluted solution of bleach (1:10 parts water) on drainage port, sleeve, cap, and connector. Also pour in bag and agitate for 30 seconds, drain, and allow to air-dry. The bag should always be rinsed with soap and water after using any disinfectant.

Source: Newman DK, *J Wound Ostomy Continence Nurs*, 34(6), 655, 2007.

Manufacturers have developed various systems for the ambulatory and bed-restricted patient. These bags can be maintained in a dependent position using straps, buttons, Velcro, and hooks. The goal is to keep the bag in a dependent position so that the urine will flow freely from the patient into the bag and not in the opposite direction (see Figure 45.4).

Cleaning drainage bags should be cleaned prior to reuse, for example, after changing from leg to night drainage. Methods [11] include the following steps:

1. Wash hands before and after bag cleansing with soap and water.
2. Disconnect bag from the catheter.
3. Run clear water through the system or use a soft squirt bottle to irrigate with water.
4. Irrigate with cleansing system with either a bleach solution *or* a vinegar solution.
5. *Bleach solution*: 1 part bleach to 10 parts water
6. *Vinegar solution*: 1 part vinegar to 3 parts water
7. Place solution in bag and tubing, irrigate for 30 seconds, and then drain.
8. Air-dry.

Be aware that bleach solution may discolor surfaces that it comes in contact with.

Drainage Valves

To facilitate emptying, the catheter and/or the bag, various spigots, and valves have been developed. These devices come in a variety of sizes that attach directly to the bag or may be inserted into the catheter. These systems provide a noncontinuous drainage system, which allows increased freedom for the patient to perform activities of daily living without a bag. When deciding if a valve is an appropriate adaptation for a patient, one must also consider the selection process as listed earlier: motivation, dexterity, level of mental capacity, and bladder functioning/capacity [13] (see Figure 45.5).

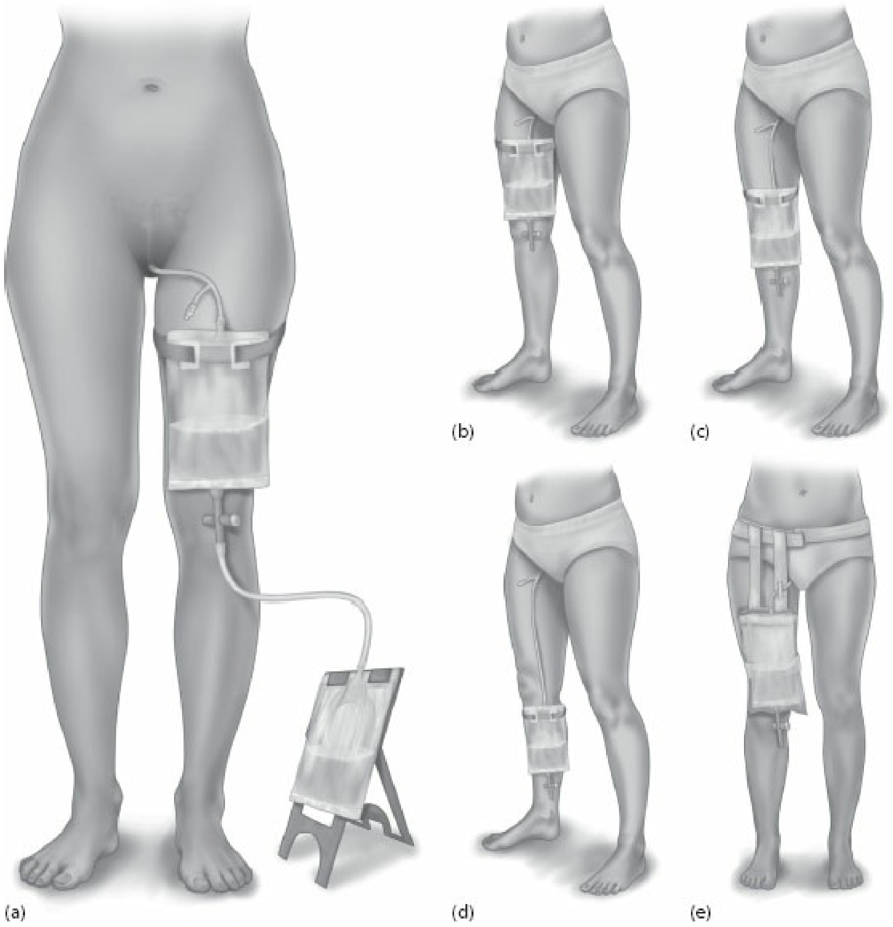

Figure 45.4 Leg bags and lengths. (a) Closed drainage system with a night bag attached to the leg bag; note the short female catheter. (b–e) Different lengths of leg bags, ranging from 350 to 750 mL in capacity, and suspensory systems: (b) short-tube bag, (c) medium-tube bag, (d) long-tube bag, and (e) alternative method of suspension.

PAD AND PANTS

Pads

Urinary incontinence can be managed by absorbent products that are known either as “body-worn” or for the protection of furniture. Body-worn systems are defined as those that are placed in undergarments. The goal of these products is to contain the urine. Other functions may include odor protection, skin protection, and avoidance of stained outer garments. Currently, pads are available in reusable/washable or single-use/disposable products. Geographic location will partially dictate the availability of different products. In some countries, pads are considered medical devices and are allocated by the government health-care system, whereas, in other countries, these products are available over the counter and consumption is consumer driven. There are very few studies, which directly compare these products with respect to efficacy, safety, or cost, and international standards do not exist.

Product design is based on numerous factors. These factors include gender and the amount of fluid to be absorbed. Female products are designed to absorb urine that drains into the middle of the undergarment. The capacity of the product’s absorption is dependent on fiber arrangement and type. Urinary incontinence pads are designed to absorb and/or contain urine and are not interchangeable with products designed to absorb menstrual waste. This is an important differentiation that should be emphasized to the patient.

Urine collection pads are designed to collect the urine from the surface of the pad and wick it away to an inner core away from the perineal skin. Currently, there is no standardization as to capacity or quality of product used in incontinence pads. Newman et al. [10] recommends some standardization for evaluation to include the following:

1. *Rewet value*: This value reflects the dryness of a product after subsequent wetting of the product when the measurement is taken at the skin level. Lower rewet values represent drier product performance.
2. *Rate of acquisition*: This is the speed at which a product is able to absorb a set volume of liquid.
3. *Total absorbent capacity*: This measurement would help delineate the differences in absorption between products that are designed for light, medium, and heavy absorbency.

   In 2012, the National Association for Continence released national (United States) standards for quality performance of disposable adult absorbent products for incontinence in the elderly, frail, and/or disabled populations [16]. These recommendations add to the three earlier for a total of eight, including the following:
4. *Sizing options*: A selection of youth and adult sizes to optimize fit and performance and reduce waste.
5. *Safety*: None of the components of the product should be deemed “unsafe” by the Federal Regulatory Agency.
6. *Presence of closure systems*: Products should incorporate a “mechanical” closure system to allow for multiple unfastening and refastening.
7. *Breathable zones*: An acceptable minimum air flow in side “wings” to release trapped body heat and gaseous body perspiration in these areas.
8. *Ability to contain fecal matter/loose stools*: Delivery of gentle, snug fit using leg and waistband elastics.

Pads are fairly uniform in their construction. Typically, there is

1. A securement layer that is an adhesive strip or strap
2. A waterproof layer to protect garments
3. A fluff layer to absorb the fluid
4. A top mesh layer to wick away the fluid from the skin

Technological advances have improved the saturation point of disposables with the addition of superabsorbent polymer (SAP). This polymer is added to the middle layer of the pad’s fluff layer, in a powder form. This hydrocolloid material changes from a powder into a gel that wicks away urine from the pad’s surface. Urine leakage outside the pad is decreased as the SAP can absorb 70 times its original weight, while maintaining a relatively small particle size of 1–2 mm.

Reusable products are made from fibers such as rayon or polyester. These options are attractive to users in that they can be used repeatedly and may provide more stability for the user. As compared to pads secured with an adhesive, these products are less likely to shift allowing for a more secure feeling of placement. The absorbent pad is fixed into the undergarment and does not lend itself to shifting from the perineal area as a disposable or removable product potentially could. They also provide the user with a more flexible quiet system without the inclusion of plastic.

Urinary leakage can be quantified per episode [10] as

- Light 0–50 mL
- Moderate 50–200 mL
- Severe greater than 300 mL

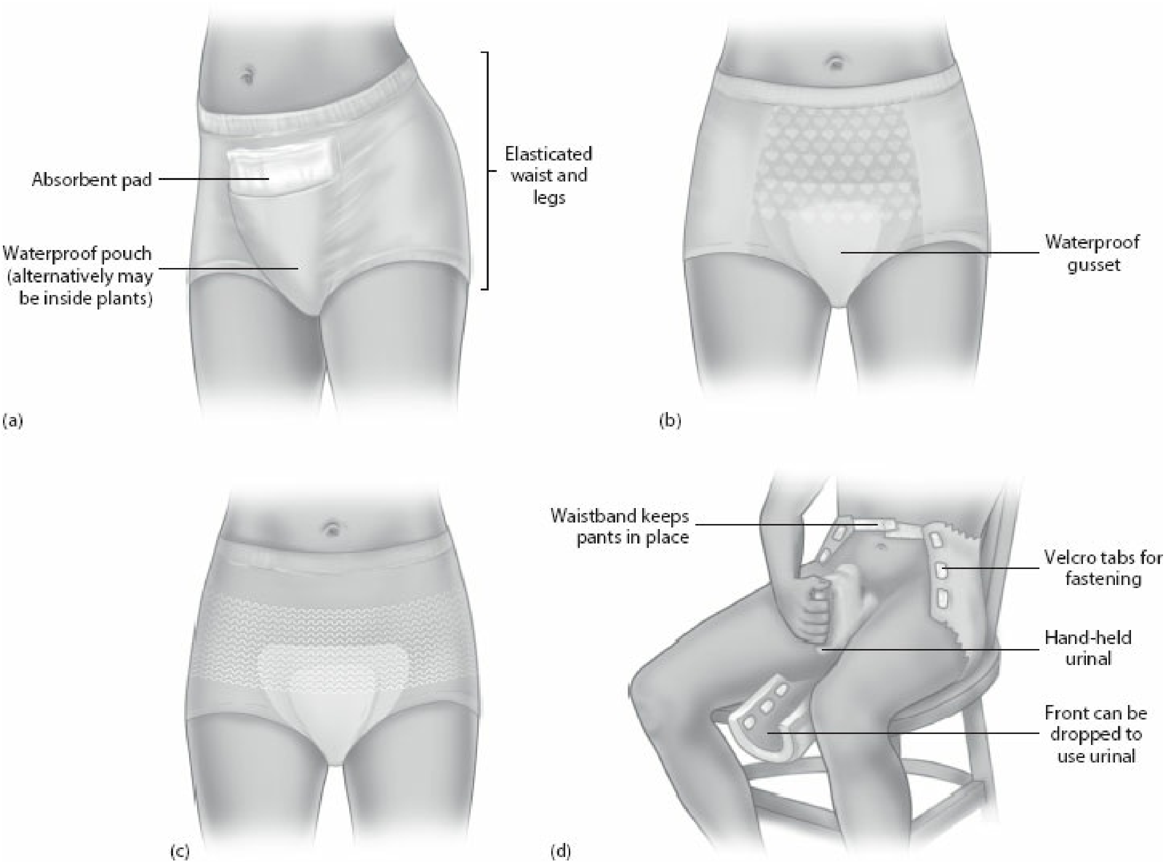
The importance of quantifying urinary leakage is that it allows the consumer to choose the smallest product for maximum benefit. It also helps health-care providers know the extent of urinary leakage per episode (Table 45.4). A Cochrane review showed that there is no strong evidence for superiority among light urinary incontinence products, disposables, or washables with respect to better skin health. There is no dominant design for cost-effectiveness although disposable pads are the most expensive. In the same review, moderate to heavy product comparison showed no single best design. Women preferred pull-ups. Washables are the least expensive [17,18].

Diaper design has been improved to include features that are specific for the female patient with incontinence needs [19]. The absorbent polymer and pulp in the front region, with a flexed convex surface in the perineal region, prevents flow toward the buttock. This design has a curled fiber–citric acid cross-linked process that helps maintain acidic skin pH, as well as air permeable side panels to minimize occlusion and results in improved incontinence-associated dermatitis (IAD) lesions [6].

Table 45.4 Pads for Undergarments

Pad type	Description	Pros	Cons
Perineal pads	Discreet options for women with light to moderate incontinence. Available in disposable and reusable products, these pads adhere to the underwear of the patient to provide body-formed protection. Generally, rectangular shaped with some differences to accommodate larger volumes, i.e., gathered edges, width changes to accommodate larger volumes.	Self-adhesive strips provide use of preexisting undergarments. Convenient: easily carried in purses to provide ease of change when out of the home environment. Pads stay in place although can be reused in the event a leakage accident does not occur. May contain built in deodorant. “Booster systems”can be used with other products to increase absorptive capacity.	Expensive May be difficult for manually dexterity-challenged patient to position
Undergarments	Form-fitting pads that are attached with elasticized, Velcro, or button fasteners.	Provides protection moderate to severe protection from urine leakage.	Often bulky and cumbersome May not be as discreet when applied under

		Available in various shapes that accommodates application in supine, sitting, and standing positioning. Soft external backing provides comfort and air exchange.	form-fitting clothing Requires large area for storage of multiple garments, more inconvenient to transport when travelling
Protective underwear	Disposable product that is pulled on, as with the cloth counterpart, but can be ripped off at the side to provide ease of removal.	Moderate to severe leakage protection. Option to provide security especially with women who may attempt to remove device when disoriented or demented. Available in systems that provide active patients to continue activities such as swimming.	Bulky, difficult to change with patient who has limited mobility or who is bed bound
Adult brief	Disposable product similar to the child's diaper provides protection with self-adhesive tabs that can be refastened and repositioned.	Moderate to severe urinary incontinence containment. Positioning ease especially with the patient who is bed bound.	Expensive Bulky Can become disheveled with frequent position changes and transfers
Pad and pant systems	Combination products using mesh or knit pants with disposable inserts for moderate incontinence.	Allows for self-toileting between changes without removal of all clothing, option for ambulatory patient. Adaptations for lingerie and nightgown options provide for apparel during intimate moments.	Inconvenience while travelling, as inserts can be bulky and nondiscreet



Absorbent pad

(a)
Waterproof gusset
(b)
(c)
Waistband keeps pants in place
Velcro tabs for fastening
Hand-held urinal
Front can be dropped to use urinal
(d)

Figure 45.6 Pouch pads and pants: (a) pouch pants, (b) stretch pants with waterproof gusset, (c) stretch pants for use with plastic-backed pad, and (d) drop-front pants.

Generally, when choosing a pad product, the woman and/or caregiver should evaluate the goals of treatment. Reviewing leakage quantity, type (urine, feces, menses), and timing may dictate changes in the padding system throughout the day and night. Typically, discreet protection coupled with ease of use while maintaining a reasonable cost will provide a product that is beneficial to meet identified goals (see Figure 45.6).

Pads for Beds and Chairs

Designed similarly to undergarment pads, these pads can be placed on furniture to provide protection. Many of these products have a nonslip backing to maintain positioning under the patient. Disposable products have lost favor to the reusable products (see Figure 45.7).

Economical and Environmental Issues

In recent years, global knowledge about the so-called “green” choices has influenced consumers on their choice of products. The reusable pad is often thought of as a more environmentally friendly alternative but considerations must be given to the by-product wastes of reuse including energy expenditures and cleaning product runoff. The downsides of disposable products include biodegradability, landfill versus incineration disposal, waste by-products, and manufacturing expenditures. Economically, both types of products have their advantages and disadvantages. The initial cost for the reusable product is usually higher, and then one must consider the cost of maintaining this product with washing, drying, and convenience for the patient and the caregiver. Ultimately, the decision for the product used will be dependent on resources available to the patient.

Skin Care

The skin is the largest organ in the human body and it has multiple functions to perform. It does these functions best when it is healthy and intact. Prevention of skin breakdown, especially in the patient with incontinence, will minimize future problems such as pain, infection, and nonhealing wounds. Inflammation of the skin from chronic exposure to urine and feces is defined as incontinence associated dermatitis (IAD). IAD presents as reddened skin with or without evidence of blisters and skin erosions. Areas involved include the skin in the perianal area, buttocks, thighs, lower abdomen, scrotum (men), labia and vulva (women), and anus. Multifactorial in origin, the study of IAD is an emerging science. Epidemiology of IAD in long-term care centers may be as high as 46% for urinary incontinence, 50% for community-dwelling adults, and 42% of hospitalized adult patients [13].

(d)

Figure 45.7 Bed pad products. Disposable and washable types of bed protection: (a) disposable bed pad and (b) washable bed sheet. Reusable bed and chair protection: (c) reusable bed pad and (d) reusable chair pad.

Skin pH

The skin has a natural acid mantle, which is a protective layer and usually maintains a pH between 4.3 and 5.9. When this pH is maintained, the integrity of the skin is maximized thus decreasing the risk of infection, breakdown, and problems associated with these maladies. When a patient is incontinent, the chronic exposure to urine and or cleaning products can change the pH to a more alkaline environment that promotes transepidermal water loss and barrier breakdown. Many commercially available cleansers are now produced that remove the incontinence debris from the perineal skin, while maintaining the normal pH. Traditionally, commercially available soaps do not offer this option and actually will slowly raise the pH of the skin with repeated usage. It is therefore recommended that patients requiring frequent cleaning during the day invest in pH-balanced cleansers. These are typically more expensive initially, but the long-term benefits will promote skin health. This point is especially sensitive for patients with dual fecal and urinary incontinence. When mixed, these substances produce urea, which further increases the alkalinity. In the presence of an alkaline environment, digestive enzymes that have not been activated will become activated outside of the gastrointestinal tract, thereby prompting further skin breakdown [20].

Skin Barriers vs. Treatments

Many commercially available products are now available for protection of the perineal skin. Prevention prior to breakdown is by far the easiest way to keep the skin intact and decrease further complications such as infection, pain, and pressure damage. Urine barriers include dimethicone, petrolatum, and skin barrier products (for example, Cavilon Spray, 3M, St. Paul, MN). These products when used prophylactically provide a physical barrier between the skin and the effluence. This barrier repels the fluid away from the skin, thus maintaining the acid mantle and decreasing maceration changes and breakdown in the epidermal layer of the skin. In the presence of stool, a zinc oxide–based barrier provides additional protection as it has the properties to repel stool effluence and maintain skin integrity. Once applied, these products do not need to be removed from the skin but cleansed and reapplied after each incontinent episode to maintain sufficient barrier protection.

Cutaneous candidiasis is also common in the patient with incontinence. Typically, candidiasis is not a microorganism that is found in the perineal skin area but can easily be deposited to this area from the gastrointestinal tract. When provided with the right environment (a moist, dark, location in an immunocompromised host), candidiasis can rapidly reproduce causing a topical cutaneous candidiasis. Treatment topically may include miconazole or clotrimazole in ointment, powder, or cream form. Treatment is usually initiated with empirical therapy when identification by observation is made. Cutaneous candidiasis is identified as a reddened rash with a confluent erythema with satellite lesions around the border. There may also be evidence of tiny fluid-filled vesicles or macules that have been opened as a result of friction from shear of clothing and pads [20].

AIDS AND APPLIANCES

Toileting Aids

Commodes

To provide access to a toilet, when a lavatory is not available or easily accessible, many freestanding commodes are available. These have such features as raised seats, adjustable legs, and chemical-emptying devices. This provides women with options to facilitate access and support independent toileting (see Figure 45.8).

Urinals for Females

Although available, these products are not used frequently. They do have some function in providing a urination receptacle for the continent patient who is not a candidate for catheter management, yet does not want pads, or many not be able to get to the toilet, such as a woman in rehabilitation for hip surgery (see Figure 45.9).

Odor Control

A good hygiene program includes adequate skin protection and control of odor. Women with incontinence tend to shower more and use additional perfumes, creams, and deodorants to conceal leakage [21]. Many women will use scented laundry detergents, which in fact may contribute to dermatitis problems as these perfumes can cause an allergic dermatitis.

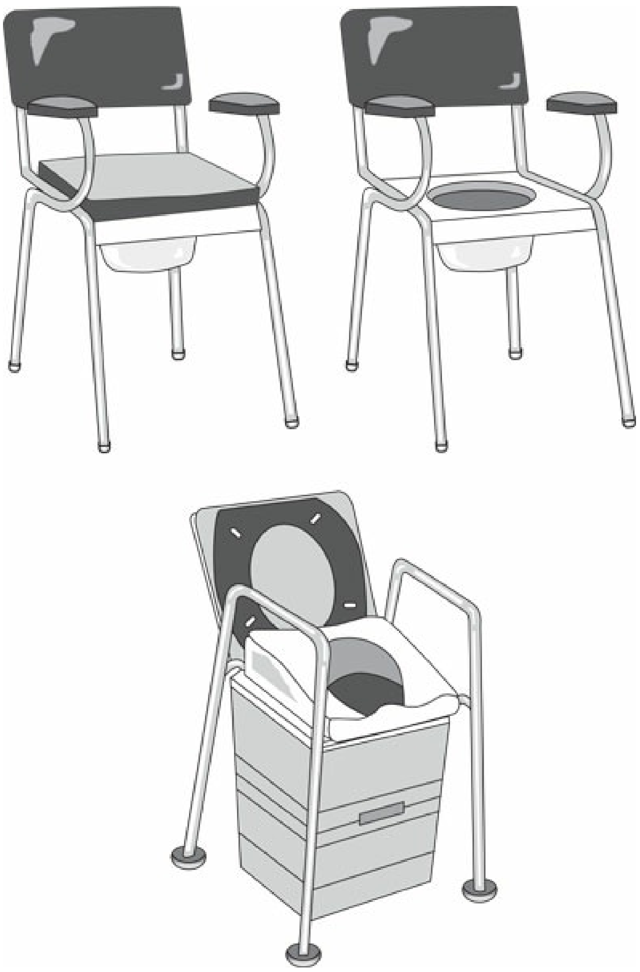

Figure 45.8 Toilet aids.

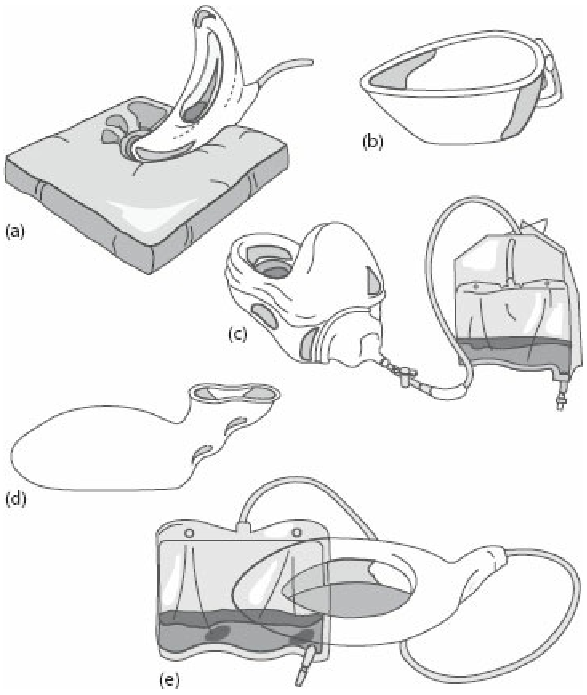

Figure 45.9 Female urinals: (a) bridge urinal with U-shaped cushion, (b) St Peter’s boat, (c) female urinal connected to drainage bag, (d) swan-neck urinal, and (e) pan-type urinal connected to drainage bag.

Assessment to control odor should include [21]

- History of devices used and current hygiene practices
- Difficulties maintaining hygiene and odor control
- Perineal assessment (skin, prolapsed, hemorrhoids, dermatitis)
- Allergies

Odor control can be accomplished by removal of the offending fluid. Also keeping the urine in an acidic state through fluid intake, the urine smell will be decreased. Various sprays are commercially available to mask the odor, without harming the skin.

RESOURCES

International Agencies

The Internet provides multiple profit and not-for-profit resources for patients, caregivers, and professionals to address the unique management needs of incontinence. The Continence Product Advisor (http://www.continenceproductadviosor.org) is an independently reviewed and written resource that uses evidence-based information on generic products, and brand name when necessary, with international links for access to products use dependent on local availability, guidelines, and regulations. The National Association for Continence provides a link on their website that is a marketplace with the latest product information (http://www.nafc.org/find-a-product/). The International Continence Society offers extensive lists on their webpage, www.icsoffice.org, about international agencies. Many of these agencies provide information on incontinence and resources to professional and lay persons about available products and guidelines for use within the said country's health-care system.

46 Drug Treatment of Lower Urinary Tract Dysfunction in Women

Ariana L. Smith, Alan J. Wein

INTRODUCTION

The lower urinary tract (LUT) has two basic functions: storage of urine and emptying of urine. These functions are achieved in two discrete phases of micturition [1].

Phase one involves filling and storage of urine in the bladder and is accomplished through the following:

1. Accommodation of increasing volumes of urine at low intravesical pressure
2. Appropriate sensation of bladder filling without allodynia
3. A bladder outlet that *is closed at rest* remains closed despite increases in intra-abdominal pressure
4. The absence of involuntary detrusor contractions (IVCs) secondary to neurogenic or nonneurogenic detrusor overactivity (DO)

Phase two involves voiding and emptying of the bladder and is accomplished through the following:

1. Coordinated contraction of the bladder smooth muscle with adequate magnitude and duration
2. Concomitant lowering of resistance at the level of the smooth and striated urethral sphincter
3. The absence of anatomic obstruction

Voiding dysfunction is a broad term that results from disruption of any one of the factors listed earlier, essentially, a failure store, a failure to empty, *or any combination of these factors*. Likewise, all treatments of voiding dysfunction can be classified under the categories of facilitating urinary storage or facilitating urinary emptying. These actions are achieved pharmacologically primarily by acting selectively or nonselectively on bladder smooth muscle or bladder outlet smooth or striated muscle. As a result of advances in the fields of neuropharmacology and neurophysiology of the LUT, effective pharmacological therapy now exists for the management of many categories of voiding dysfunction. In fact, in some categories, so many drug therapies are available for use with varying quality and quantity of research performed on them, and the International Consultation on Incontinence has assessed and made recommendations on many of the available agents (Tables 46.1 [updated] and 46.2 [updated]). The clinical drug recommendations are based on evaluations made using a modification of the Oxford system (Table 46.3).

CLINICAL UROPHARMACOLOGY OF THE LOWER URINARY TRACT

LUT uropharmacology addresses the innervations and receptor contents of the bladder, urethra, and pelvic floor. The targets of pharmacological intervention include not only these structures but also the peripheral nerves and ganglia that supply these tissues and the central nervous system (CNS), including the spinal cord and supraspinal areas. Specifically, pharmacological targets include nerve terminals that alter the release of neurotransmitters, receptor subtypes, cellular second messenger systems, and ion channels. The autonomic nervous system assumes primary control over the two functions of the LUT; however, due to its lack of specificity and ubiquitous nature of its receptors, there are no pharmacological agents that are purely selective for the LUT. Consequently, side effects of the treatment are common and are the result of collateral effects on organ systems that share some of the same neurophysiological or pharmacological characteristics as the bladder and urethra.

Our approach to pharmacological management is to start with the simplest and least perilous form of treatment first. After appropriate dose escalation, other, potentially more toxic, therapeutic options can be offered. Alternatively, a combination of agents or drugs can be used, ideally with synergistic mechanisms of action and nonsynergistic side effects. In our experience, although great improvement can occur with rational pharmacological therapy, a perfect result, i.e., the restoration to normal function, is seldom achieved.

FACILITATION OF URINE STORAGE

Failure of the LUT to adequately fill and store urine may be secondary to pathology in the bladder, the outlet, or both [2]. The most common etiology in women is DO that manifests symptomatically as overactive bladder (OAB), a syndrome of urgency, with or without urge urinary incontinence (UUI), which may be associated with frequency and nocturia [3]. DO includes IVCs of the bladder, discrete or phasic, and decreased compliance. IVCs are commonly associated with neurological disease, inflammatory processes of the bladder, bladder outlet obstruction (BOO), and aging, can be stress induced, or may be idiopathic. Decreased compliance is usually the sequelae of neurological disease but may also result from any process that destroys the elastic or viscoelastic properties of the bladder wall. The treatment for these conditions is aimed at decreasing bladder activity or increasing bladder capacity.

Heightened or altered sensation of the bladder may manifest as urgency with or without DO or as painful bladder syndrome. This may result from inflammatory, infectious, neurological, or psychological factors, or it may be idiopathic. Therapy is aimed at increasing bladder capacity or decreasing sensory (afferent) input. The various therapeutic options for painful bladder syndrome will be dealt with in a separate chapter.

Table 46.3 International Consultation on Incontinence (ICI) Assessments 2008: Oxford Guidelines (Modified)

Levels of evidence

Level 1: Systematic reviews, meta-analyses, good-quality RCTs

Level 2: RCTs, good-quality prospective cohort studies

Level 3: Case-control studies, case series

Level 4: Expert opinion

Grades of recommendation

Grade A: Based on level 1 evidence (highly recommended).

Grade B: Consistent level 2 or 3 evidence (recommended).

Grade C: Level 4 studies or “majority evidence” (optional).

Grade D: Evidence is inconsistent/inconclusive (no recommendation possible) or the evidence indicates that the drug should not be recommended.

Source: Andersson K-E et al., Pharmacological treatment of urinary incontinence, in: Abrams P et al., eds., *Incontinence, 5th International Consultation on Incontinence*, ICUD-EAU, 2013, pp. 623–728. With permission.

Decreased outlet resistance may manifest from damage to the smooth or striated sphincter secondary to surgical, obstetric, or other mechanical trauma or degeneration of innervation with the loss of neuronal mass secondary to neurological disease, aging, or trauma [4]. In addition, in women, it may result from decreased pelvic floor support of the bladder outlet. Clinically, this manifests as an effort related or stress urinary incontinence (SUI) or, when severe, as complete gravitational incontinence. Treatment is aimed at increasing outlet resistance.

Disruption in the filling and storing function of the bladder can, in theory, be improved by agents that decrease detrusor activity, increase bladder capacity, decrease sensory input, or increase outlet resistance [2].

Decreasing Bladder Contractility

Antimuscarinic Agents

Physiological bladder contractions are thought to be primarily triggered by acetylcholine (ACh)-induced stimulation of postganglionic parasympathetic muscarinic cholinergic receptor sites on bladder smooth muscle [1,5]. Atropine and other antagonists of ACh that bind these receptor sites will depress normal bladder contractions and IVCs of any cause [5,6]. In addition, these agents increase the volume to first IVC and the total bladder capacity and decrease the amplitude of the contraction [7]. The commonly held belief regarding antimuscarinic drugs is that they bind receptors on the detrusor that are stimulated by ACh, thereby decreasing the ability of the bladder to contract. However, during bladder filling and storage, there is no sacral parasympathetic outflow [8], which raises the following question: “Why do antimuscarinics affect the filling/storage phase of the micturition cycle, increasing, in patients with OAB and without DO, bladder capacity and decreasing urgency?” Muscarinic receptors are also present in the bladder urothelium and suburothelium [9], and there is a basal ACh release in human detrusor muscle that may be produced, at least partly, by the urothelium and suburothelium [10]. This suggests that detrusor tone may be affected by ongoing ACh-mediated stimulation. There is now good direct experimental evidence that the antimuscarinics decrease activity in both C- and A-delta afferent nerve fibers from the bladder during filling/storage [11,12].

ACh acts on two classes of receptors, nicotinic and muscarinic. Signal transduction between parasympathetic nerves and smooth muscle of the detrusor involves muscarinic receptors [13]. At least five different muscarinic receptor subtypes exist, which are designated M_1–M_5. Although it appears that the majority of the muscarinic receptors in human smooth muscle are of the M_2 subtype, in vitro data indicate that most smooth muscle contraction, including that of the bladder, is mediated by the M_3 receptor subtype. The muscarinic receptors are found not only on smooth muscle cells of the bladder but also on urothelial cells, on suburothelial nerves, and on suburothelial structures such as interstitial cells with a M_2 and M_3 preponderance [9]. Based on the work in animals, the M_2 receptors have been implicated in the contraction of diseased bladders (denervated, hypertrophied rat bladders) [11].

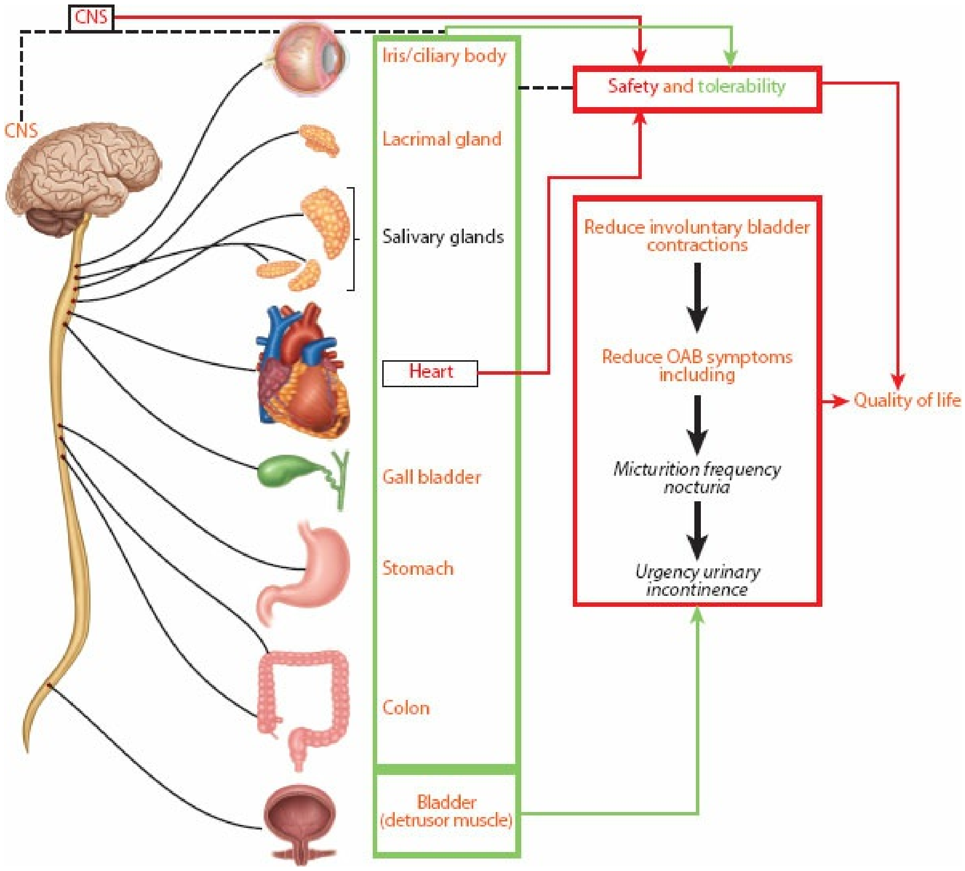
Antimuscarinics can be divided into tertiary and quaternary amines, which differ in molecular size, molecular charge, and lipophilicity [13]. Small molecular size with little charge and greater lipophilicity increase the passage through the blood–brain barrier with the theoretical potential of greater CNS side effects. Tertiary compounds have higher lipophilicity and less molecular charge than quaternary agents. Quaternary compounds have greater molecular charge and less lipophilicity resulting in limited passage into the CNS and a low incidence of CNS side effects [14].

A meta-analysis on antimuscarinic agents found that these agents are more effective than placebo in improving continent days, mean voided volume, urgency episodes, and micturition frequency [15]. The vast majority of agents studied provided improvement in health-related quality of life (HRQL). Across large patient samples, all of the currently available antimuscarinics appear to have comparable efficacy but do show some measurable differences in tolerability [16]. Since the profiles of each drug and the dosing schedules differ, these things along with medical comorbidities and concomitant medications should be considered when individualizing treatment for patients.

The currently available antimuscarinic drugs lack selectivity for the bladder and as a result produce side effects on other organ systems (Figure 46.1). The most common adverse effects include dry mouth, blurred vision, pruritus, tachycardia, somnolence, impaired cognition, and headache. Constipation is reported as the most burdensome side effect [15]. This class of drug is contraindicated in patients with urinary retention, gastric retention, and other severe decreased gastrointestinal motility conditions and uncontrolled narrow-angle glaucoma. The concomitant use with other anticholinergic agents may increase the frequency and/or severity of these effects. Specific patient populations including those with renal or liver impairment and those with genetic heterogeneity in drug-metabolizing enzymes may experience increased side effects due to altered pharmacokinetic behavior of a given drug [16]. Many of these drugs should not be used with potent cytochrome P450 (CYP) 3A4 inhibitors including ritonavir, ketoconazole, itraconazole, verapamil, and cyclosporine [17–20].

It is estimated that about one-third of all patients with OAB have at least one risk factor for altered drug metabolism [16]. While relative muscarinic receptor selectivity exists for some agents, there is no uroselective option that avoids unpleasant systemic side effects. As a result, patient compliance is extremely low and the search for uroselectivity continues. Intravesical administration, in the absence of systemic absorption, would greatly diminish the antimuscarinic side effects; however, this is practical only in patients who perform clean intermittent catheterization (CIC).

Antimuscarinic agents are considered first-line pharmacotherapy for OAB [21]. Specific antimuscarinic drugs are listed as follows with available data on efficacy and comparative efficacy with other drugs in class.



CNS
CNS
Iris/ciliary body
Safety and tolerability
Lacrimal gland
Salivary glands
Reduce involuntary bladder contractions
Heart
Reduce OAB symptoms including
Quality of life
Micturition frequency nocturia
Gall bladder
Stomach
Urgency urinary incontinence
Colon
Bladder (detrusor muscle)

Figure 46.1 Important sites of action of antimuscarinics. Abbreviations: CNS, central nervous system; OAB, overactive bladder. (Adapted from Andersson K-E et al., Pharmacological treatment of urinary incontinence, in: Abrams P et al., eds., *Incontinence, 5th International Consultation on Incontinence*, ICUD-EAU, 2013, pp. 623–728.)

Atropine

Atropine, along with hyoscyamine and scopolamine, is active belladonna alkaloids, derived from the toxic belladonna plant with anticholinergic properties [12]. Atropine has significant systemic side effects including ventricular fibrillation, tachycardia, dizziness, nausea, blurred vision, loss of balance, dilated pupils, photophobia, extreme confusion, and dissociative hallucinations, which limit its oral use for the treatment of OAB. Intravesical atropine at a dose of 6 mg four times per day was shown to be as effective as intravesical oxybutynin (OXY) for increasing bladder capacity with minimal systemic side effects in patients with multiple sclerosis in a double-blind, randomized placebo-controlled trial (RCT) with crossover design [22]. Its mention in this chapter is more of a historic one.

Darifenacin

Darifenacin is a tertiary amine with moderate lipophilicity and is a relatively selective M_3 receptor antagonist. At least theoretically, darifenacin's advantage is the ability to relatively selectively block the M_3 receptor that although less prevalent than the M_2 receptor appears to be more important in bladder contraction. This selectivity is expected to increase efficacy in patients with OAB while reducing the adverse events related to the blockade of other muscarinic subtypes [23]. Darifenacin has been developed as a controlled release formulation to allow daily dosing and is available at 7.5 and 15 mg/day. Several RCTs have documented the clinical effectiveness of the drug. Haab et al. performed a multicenter, double-blind RCT comparing darifenacin 3.75, 7.5, 15 mg and placebo once daily for 12 weeks [24]. The study enrolled 561 patients (85% female) age 19–88 years with OAB symptoms for at least 6 months and included patients with prior exposure to antimuscarinic therapy. The 7.5 and 15 mg doses of darifenacin had rapid onset of effect with significant improvement in symptoms over placebo at 2-week follow-up. The clinical parameters in which the treatment arm was significantly better than placebo included micturition frequency, bladder capacity, frequency of urgency, severity of urgency, and number of incontinence episodes. No significant change in nocturia was seen. The most common side effects were mild to moderate dry mouth and constipation. The CNS and cardiac safety profiles were similar to placebo. Discontinuation was rare.

A review of the pooled data from three phase III, multicenter, double-blind RCTs was performed by Chapple et al. in 2005 [25]. A total of 1059 patients (85% female) with urgency, UUI, and frequency were treated with darifenacin 7.5, 15 mg or placebo daily for 12 weeks. Significant dose-related improvements in number of incontinence episodes per week were seen: 8.8 less episodes per week with the 7.5 mg dose and 10.6 less episodes per week with the 15 mg dose. Improvements in micturition frequency, bladder capacity, and severity of urgency were also seen. The most common side effects were dry mouth and constipation resulting in few discontinuations.

The ability to postpone urination is one of the most noticeable clinical effects of antimuscarinic therapy. Often, measured as "warning time," which is defined as the time from first sensation of urgency to the time of voluntary micturition or incontinence, the ability to postpone a few extra minutes can be the difference between wet and dry. Cardozo and Dixon performed a multicenter, double-blind RCT looking at the effects of darifenacin on warning time [26]. Overall, 47% of the darifenacin group compared to 20% of the placebo group achieved a >30% increase in mean warning time. The patients in this study received a 30 mg dose of darifenacin, which is higher than the clinically recommended dose. These results have not been replicated using the 15 mg dose.

Darifenacin has been shown to improve HRQL sustained at 2 years of treatment [310].

The effects of darifenacin on cognitive function in elderly volunteers were tested in a randomized, double-blind, three-period crossover study with 129 patients 65 years of age or older [27]. After 2 weeks of treatment, no effect on cognitive function compared with baseline was found. The authors hypothesized that this was related to its M_3 receptor selectivity. Further studies on the blood–brain barrier by Chancellor et al. indicate that darifenacin, along with trospium and fesoterodine, is actively transported away from the brain as the result of a protein-mediated transport system [303]. Darifenacin has not been found to have any effect on QT/QTc intervals or heart rate compared to placebo [334,341].

Fesoterodine

Fesoterodine is a newer antimuscarinic drug that is metabolized rapidly and extensively to 5-hydroxymethyl tolterodine (5-HMT), the same active metabolite of tolterodine (TOLT) [28]. Fesoterodine relies on nonspecific esterases that produce a rapid and complete conversion to 5-HMT with little pharmacokinetic variability. 5-HMT is further metabolized in the liver, but a modest percentage of 5-HMT undergoes renal excretion without additional metabolism, raising the possibility that 5-HMT could also work from the luminal side of the bladder [29]. Whether this contributes to clinical efficacy in human remains unknown at this time. Like TOLT, this compound is a nonsubtype selective muscarinic receptor antagonist [30]. The 4 mg/day dose can be used in patients with moderately impaired renal or hepatic function since there is dual metabolism of 5-HMT by both organ systems [307,320].

Fesoterodine is indicated for the treatment of DO at doses of 4 and 8 mg daily. In a multicenter, double-blind, double-dummy RCT with TOLT extended release (ER), 1132 patients were enrolled and received treatment [28]. The trial showed that both the 4 and 8 mg doses of fesoterodine were effective in improving the symptoms of OAB with the 8 mg dose having greater effect at the expense of a higher rate of dry mouth. Only one subject from the fesoterodine 8 mg group and one subject from the TOLT ER 4 mg group withdrew from the study due to dry mouth. The dose–response relationship was confirmed in another study that pooled data from two phase III RCTs [31]. Fesoterodine 8 mg performed better than the 4 mg dose in improving urgency and UUI as recorded by 3-day bladder diary, offering the possibility of dose titration. A study on the effect of fesoterodine on HRQL in patients with OAB confirmed improvement for both the 4 and 8 mg dose of the drug [32]. A head-to-head placebo-controlled trial comparing fesoterodine 8 mg to TOLT ER 4 mg (n = 1590) showed greater improvements in urgency incontinence episodes, completely dry rates, voided volume, and patient perception of improvement with fesoterodine [315]. No difference was noted in frequency of micturition and urgency episodes. Significantly, greater side effects (dry mouth, headache, constipation, and discontinuation) were reported with fesoterodine. This study suggests that fesoterodine 8 mg can provide improved symptom control over TOLT ER. In a large double-blind, double-dummy, phase III study (n = 2417), fesoterodine 8 mg showed greater improvement in urgency incontinence episodes, frequency of micturition, urgency episodes, and patient perception of improvement than TOLT ER 4 mg or placebo [323]. No difference in voided volume or nocturia was noted. Dry mouth, constipation, and discontinuation rates were greater with fesoterodine 8 mg. Fesoterodine has not been found to prolong QT/QTc or produce other cardiac abnormalities [321].

Hyoscyamine

Hyoscyamine is a pharmacologically active antimuscarinic component of atropine that is reported to have similar actions and side effects [12]. Few clinical studies are available to evaluate efficacy in the treatment of DO [33]. A sublingual formulation of hyoscyamine sulfate is available.

Imidafenacin

Imidafenacin is a muscarinic antagonist with greater affinity for the M_3 and M_1 receptors than the M_2 receptor [326]. The oral administration of imidafenacin in rats showed longer-lasting and more selective binding to muscarinic receptors in the bladder than other tissues, with little binding in the brain [352]. Whether this translates to its pharmacological effects on humans remains unknown. The drug is primarily metabolized in the liver by cytochrome P450 enzyme CYP3A4 [322]. The drug is also excreted in the urine; however, the pharmacological importance of this has not yet been elucidated.

Clinical studies have primarily been performed in Japan and the drug is not available in Western countries. A randomized, double-blind, placebo-controlled phase II study (n = 401) showed a dose-dependent reduction in urgency incontinence episodes that was significant over placebo [318]. In addition, frequency of micturition, urgency episodes, and voided volume were significantly improved. In a larger study, the same authors performed a placebo- and propiverine-controlled trial (n = 781) that demonstrated noninferiority of imidafenacin compared to propiverine for the reduction of urgency incontinence episodes [317]. The incidence of side effects was significantly lower with imidafenacin than propiverine. A long-term 52-week study by the same authors (n = 376) demonstrated a persistent improvement in voiding symptoms with the most common adverse event being dry mouth in 40.2% [316]. Imidafenacin has not been found to prolong QT/QTc or alter vital signs, laboratory values, or postvoid residual (PVR) measures.

Propantheline Bromide

The classic oral agent for antimuscarinic effects on the LUT was propantheline bromide, a nonselective quaternary ammonium compound that is poorly absorbed after oral administration [12]. It has a short plasma half-life of <2 hours and varying biological availability requiring individual titration. It is initially prescribed at 15–30 mg four times daily, but larger doses are often required [34]. Despite having antimuscarinic binding potential quite similar to atropine, there is a lack of convincing data on the effectiveness for the treatment of OAB/DO. Contradictory studies are available that show complete response in 25/26 patients [35] and no difference from placebo in 154 and 23 patients, respectively [36,37]. By today's standards, the effect of propantheline on DO has not been well documented in RCTs; however, with its long history of use, it can be considered effective and may, in individually titrated doses, be clinically useful.

Scopolamine

Scopolamine, a belladonna alkaloid, has greater penetration through the blood–brain barrier than atropine and as a result produces more prominent central depressive effects even at low doses [12]. Transdermal scopolamine has been used for treating DO at a continuous dose of 0.5 mg for 3 days [38]. A double-blind RCT was performed in 20 patients with DO. After 14 days, patients in the treatment group showed significant improvements in frequency, nocturia, urgency, and UUI over the placebo group. Side effects included dizziness, ataxia, blurred vision, dry mouth, and skin irritation at patch site. No patients discontinued use during the study period [33].

Solifenacin

Solifenacin is a tertiary amine with modest selectivity for the M_3 receptor over the M_2 and marginal selectivity over the M_1 receptors [13,39]. Solifenacin is metabolized in the liver utilizing the cytochrome P450 enzyme system (CYP3A4), but a modest percentage undergoes renal excretion without additional metabolism raising the possibility that solifenacin could also work from the luminal side of the bladder. Whether this contributes to clinical efficacy in humans remains unknown at this time. Studies have demonstrated that solifenacin increases maximum bladder capacity and area under the bladder volume sensation curve [327,344]. It is a once-daily antimuscarinic that is being marketed at the 5 and 10 mg doses. There have been several large trials examining the effects of solifenacin. A large, phase II, multinational RCT was performed comparing solifenacin 2.5, 5, 10, and 20 mg daily to TOLT immediate release (IR) 2 mg twice daily and placebo [40]. A total of 225 patients with urodynamically confirmed DO were enrolled, treated for 4 weeks, and followed for two additional weeks. There was a significant decrease in micturition frequency, incontinence episodes, and urgency episodes, and an increase in volume voided in the 5, 10, and 20 mg solifenacin groups compared to placebo. The mean effects with TOLT were generally smaller as compared to solifenacin. The 5 and 10 mg doses of solifenacin had a lower dry mouth rate than TOLT. Discontinuation rates were highest for solifenacin 20 mg.

Cardozo and colleagues performed a multinational RCT comparing solifenacin 5 and 10 mg daily to placebo in 857 patients [41]. Both doses significantly improved micturition frequency, urgency, volume voided, and incontinence episodes compared to placebo as determined by the 3-day micturition diaries. Of patients who reported any incontinence at baseline, 50% achieved continence after treatment with solifenacin compared with 27.9% after placebo. Dry mouth was reported in 7.7% of patients taking solifenacin 5 mg, 23.1% in solifenacin 10 mg, and 2.3% in the placebo arm. Only a small percentage of patients (2%–4%) did not complete the study due to adverse events and this was comparable in all groups.

The solifenacin and TOLT as an active comparator in a randomized trial was a prospective double-blind, parallel group 12-week study comparing solifenacin 5 and 10 mg once daily to TOLT ER 4 mg once daily [42]. After 4 weeks of treatment, patients were given the option to increase medication dosage. However, only those on solifenacin actually received the dose increase. The results showed noninferiority of solifenacin's flexible dosing regimen compared to TOLT ER for voiding frequency. Solifenacin showed increased efficacy in decreasing urgency episodes, incontinence, and pad usage compared with TOLT ER. Additionally, more solifenacin patients achieved dryness, as documented by 3-day voiding diary, by the end of the study (59% vs. 49%). However, these symptomatic improvements were accompanied by an increase in adverse events with dry mouth and constipation occurring in 30% and 6.4% of the solifenacin group, respectively, versus 23% and 2.5% in the TOLT group. The discontinuation rate was comparably low in both groups.

A systematic review and meta-analysis of 9 RCTs concluded that solifenacin provides significant improvement in voiding symptoms compared to placebo or TOLT [329]. Solifenacin 10 mg was better than 5 mg in reducing frequency of micturition. Constipation and blurred vision were greater with solifenacin as compared to TOLT.

The efficacy in mixed urinary incontinence [43], the elderly [44], and in multiple sclerosis patients [348] has been shown, as has an improvement in HRQL [45].

Data on solifenacin treatment in children are limited. An open-label study including 72 children of which 27 had neurogenic bladder demonstrated improved urodynamic capacity and improved continence [299].

Solifenacin has shown QT interval prolongation and torsade de pointes in an 81-year-old female [297]. In a large open-label postmarketing study (n = 4450) including patients with cardiovascular comorbidities and comedication, solifenacin did not demonstrate any clinically relevant alteration in blood pressure or heart rate [332].

Tolterodine

TOLT is a tertiary amine with a major active metabolite, 5-HMT, which significantly contributes to the therapeutic effect of the drug [46]. Both TOLT and its metabolite have plasma half-lives of 2–3 hours, but their effects on the bladder seem to be more long lasting. Whether this could be the result of urinary excretion of the drug with direct bladder mucosal effects remains unknown. TOLT does not have muscarinic subtype selectivity but there is evidence in some experimental models that it has functional selectivity for the bladder over the salivary glands [47]. This has been shown in the guinea pig where the binding affinity of TOLT and OXY to muscarinic receptors in the bladder were very similar, but the affinity of TOLT for muscarinic receptors in the parotid gland was eight times lower than that of OXY [48]. TOLT is available in two formulations: an IR form prescribed as 2 mg twice daily and an ER form prescribed as 2 or 4 mg once daily. There appears to be advantages in both efficacy and tolerability with the ER form [49]. There appears to be a very low incidence of cognitive side effects with TOLT, which is likely due to the low lipophilicity of the drug and its metabolite, minimizing penetration into the CNS [50]. A notable subset of patients, up to 10% of whites and up to 19% of blacks, lack the specific CYP enzyme, 2D6, that metabolizes TOLT to 5-HMT [51]. In these patients, a higher side-effect profile, specifically including sleep disturbance, is seen [52]. Drugs that do not require CYP2D6 metabolism have the potential for less pharmacokinetic variability.

The efficacy of TOLT has been documented by several double-blind RCT on patients with DO. The Overactive Bladder: Judging Effective Control and Treatment (OBJECT) trial compared TOLT IR 2 mg twice daily to OXY ER 10 mg daily [53]. This was a double-blind, parallel group RCT, which included 378 patients with OAB treated for 12 weeks. The study showed OXY ER to be significantly more effective than TOLT in reducing UUI episodes, total incontinence, and micturition frequency. The most common adverse event, dry mouth, was reported in 28% of those taking OXY ER and 33% of those taking TOLT IR. The rates of other adverse events including CNS effects were generally low and comparable between the groups.

The Overactive Bladder: Performance of Extended Release Agents (OPERA) trial compared TOLT ER 4 mg daily to OXY ER 10 mg daily in 790 women with OAB symptoms [54]. This was a double-blind RCT with duration of 12 weeks. Improvements in UUI episodes were similar between the two groups but cure of UUI was greater in the OXY ER group (23.0% vs. 16.8%). OXY ER was also more effective in reducing micturition frequency at the price of increased rates of dry mouth. Adverse events were mild and occurred at low rates, with both groups having similar rates of discontinuation of treatment.

The antimuscarinic clinical effectiveness trial was an open-label study of 1289 patients with OAB comparing TOLT ER 2 or 4 mg daily to OXY 5 or 10 mg daily [55]. After 8 weeks, 70% of patients taking TOLT ER 4 mg perceived an improved bladder condition compared to 60% in the TOLT ER 2 mg group, 59% in the OXY ER 5 mg group, and 60% in the OXY ER 10 mg group. Dry mouth was dose dependent with both drugs; however, patients treated with TOLT ER 4 mg reported a significantly lower severity of dry mouth compared with OXY ER 10 mg. Fewer patients withdrew from the TOLT ER 4 mg group (12%) than either the OXY ER 5 mg group (19%) or the OXY ER 10 mg group (21%).

Although the findings suggest that TOLT ER 4 mg may have improved clinical efficacy and tolerability to OXY ER 10 mg, the open-label design of this study makes for a less convincing conclusion.

In the Improvement in Patients: Assessing Symptomatic Control with TOLT ER study, the efficacy of TOLT in improving patients' most bothersome symptoms was assessed [56]. It found significant reduction in bothersome symptoms whether it be incontinence, urgency episodes, or micturition frequency. Dry mouth occurred in 10% of patients and constipation in 4%.

Conflicting data exist on the concomitant use of TOLT and pelvic floor muscle training. In a prospective, open study of 139 women with OAB who were randomized to TOLT, bladder training or both, combination therapy was found to be most effective [57]. Similarly, a multicenter, single-blind study of 505 patients comparing TOLT alone to TOLT plus bladder training concluded that the effectiveness of TOLT can be augmented with the addition of a bladder training regimen [58]. However, a similar multinational RCT including 480 patients concluded that no additional benefit was seen with the addition of pelvic floor muscle exercises to TOLT [59].

TOLT ER has shown a significant increase in the heart rate in a proportion of subjects, and this effect was not seen with darifenacin or placebo [334]. In a study of solifenacin versus TOLT ER, similar therapeutic and urodynamic effects were noted but TOLT had a greater effect on increasing heart rate [319].

Trospium

Trospium is a hydrophilic, quaternary amine with limited ability to cross the blood–brain barrier. This should result in minimal cognitive-related dysfunction [60] and has demonstrated undetectable levels in the cerebral spinal fluid on day 10 of use [343]. Trospium does not have muscarinic subtype selectivity and, unlike the previous antimuscarinics mentioned, is not metabolized by the CYP enzyme system. It is mainly eliminated unchanged in the urine by renal tubular secretion, and as a result, may affect the urothelial mucosal signaling system as has been shown in the rat [61]. Whether this contributes to clinical efficacy in humans remains unknown at this time. In a multicenter, double-blind RCT, the effect of trospium on urodynamic parameters was studied in patients with neurogenic DO secondary to spinal cord injury (SCI) [62]. A 20 mg dose was given twice daily for 3 weeks. An increase in maximum cystometric capacity and compliance and a decrease in maximal detrusor pressure were seen in the treatment group. A similar study compared the use of trospium and OXY in the treatment of neurogenic DO [63]. Both medications appeared to have equal effect, but the patients on trospium had fewer side effects. The effectiveness of trospium in the treatment of nonneurogenic DO has also been well documented. Allousi et al. performed a double-blind RCT comparing trospium 20 mg twice daily to placebo in 309 patients [64]. At 3 weeks, urodynamic studies revealed an increase in maximum bladder capacity and volume at first IVC in the trospium group. In a study comparing the efficacy of trospium 20 mg twice daily with TOLT 2 mg twice daily and placebo in 232 patients with DO or mixed urinary incontinence, Jünemann and Al-Shukri found trospium to be significantly more effective in decreasing the frequency of micturition than either TOLT or placebo [65]. Additionally, trospium caused a greater reduction in incontinence episodes with a similar rate of dry mouth as TOLT.

A long-term tolerability and efficacy study comparing trospium 20 mg twice daily and OXY 5 mg twice daily in 358 patients with DO undergoing treatment for 52 weeks was performed [66]. Urodynamics and patient-recorded voiding diaries were performed at baseline, 26 weeks, and 52 weeks. Mean maximum cystometric capacity increased in the trospium group by 92 mL at 26 weeks and by 115 mL at 52 weeks. No other significant urodynamic differences were seen between the groups. The micturition diaries indicated a reduction in micturition frequency, incontinence frequency, and urgency episodes in both treatment groups. At least one adverse event occurred in the majority of patients: 64.8% in the trospium group and 76.6% in the OXY group. The most common side effect in both groups was dry mouth. Overall, both drugs were comparable in the efficacy in improving urinary symptoms, but trospium had a better benefit/risk ratio than OXY due to better tolerability.

An ER formulation of trospium, 60 mg once daily, has been shown in RCTs to have similar efficacy and side effects as the twice daily preparation [67]. An analysis of patients 75 years of age and older (n = 143) showed improvement in all voiding diary parameters and quality of life in patients on trospium ER compared to controls [339]. No CNS adverse effects were reported during the 12-week study; however, during the 9-month open-label follow-up, one patient reported dizziness and one reported vertigo thought to be possibly related to trospium ER.

Intravesical installation of trospium was studied with a single-center, single-blind RCT with 84 patients [68]. Since intravesical trospium does not seem to be absorbed, an opportunity exists for treatment with minimal systemic antimuscarinic effects [69]. Compared to placebo, intravesical trospium produced a significant increase in maximum bladder capacity and a decrease in detrusor pressure. No improvement in uninhibited bladder contractions was seen. No adverse events were reported, but an increase in residual urine was noted. Trospium has not been reported to result in cognitive dysfunction.

Dual Musculotropic Relaxants: Antimuscarinic Agents

Some agents have been identified that have dual mechanisms of action. They have antimuscarinic activity and direct musculotropic relaxant effects on the bladder smooth muscle at a site metabolically distal to the antimuscarinic receptor. It is felt that the clinical effects of these drugs are primarily explained by an antimuscarinic action.

Flavoxate

Flavoxate also has direct inhibitory action on smooth muscle along with very weak anticholinergic properties [70]. The drug has also been found to possess moderate calcium antagonistic activity, exhibit local anesthetic properties, and have the ability to inhibit phosphodiesterase (PDE) [71]. In rats and in cats, there is some evidence that flavoxate may also have central effects on the inhibition of the micturition reflex [72,73].

Clinical studies addressing the efficacy of flavoxate in the treatment of OAB/DO have been mixed. In a double-blind crossover study comparing flavoxate 1200 mg daily with OXY 15 mg daily in 41 women with idiopathic DO, both drugs had similar efficacy with flavoxate having fewer and milder side effects [74]. A very small study in the elderly population with nonneurogenic DO showed flavoxate had essentially no effect on cystometric capacity and incontinence [75]. Chapple et al. also suggest no beneficial effect of flavoxate in the treatment of idiopathic DO [76]. In general, few side effects were reported during treatment. No recent RCTs addressing the efficacy of this drug have been performed.

Oxybutynin

OXY is a moderately potent antimuscarinic agent that has strong independent musculotropic relaxant activity as well as local anesthetic activity (that is likely only important during intravesical administration). It is a tertiary amine that is metabolized primarily by the CYP system into its primary metabolite, *N*-desethyloxybutynin (DEO) [77]. The recommended oral adult dose for the IR formulation is 5 mg three or four times daily. An ER once-daily oral formulation as well as a transdermal delivery system (TDS) with twice weekly dosing and a transdermal gel with once-daily dosing is available. Side effects are secondary to nonspecific muscarinic receptor binding.

Initial reports documented success in depressing neurogenic DO [78], and subsequent reports documented success in inhibiting idiopathic DO as well [79]. A meta-analysis summarizing 15 RCTs ($n = 476$) reported a 52% mean reduction in incontinence episodes, a 33% mean reduction in micturition frequency, and a 74% mean overall improvement rate. This came at the expense of a 70% of patients experiencing an adverse event [80].

Holmes and associates compared the results of OXY and propantheline in a small group of women with DO [37]. The experimental design was a randomized crossover trial with a patient-regulated variable dose regimen. This kind of dose titration study allows the patient to increase the drug dose to whatever is perceived to be the optimum ratio between clinical improvement and side effects. Of the 23 women in the trial, 14 reported subjective improvement with OXY as opposed to 11 with propantheline. Both drugs significantly increased the maximum cystometric capacity and reduced the maximum detrusor pressure on filling. The only significant objective difference was a greater increase in the maximum cystometric capacity with OXY. The mean total daily dose of OXY tolerated was 15 mg (range 7.5–30 mg) and that of propantheline was 90 mg (range 45–145 mg).

The therapeutic effect of OXY IR is associated with a high incidence of side effects, which are often dose limiting [81]. The ER form of OXY uses an osmotic system to release the active compound at a controlled rate over a period of 24 hours. As a result, there is less absorption in the proximal portion of the gastrointestinal tract and less first-pass metabolism. By decreasing the liver metabolite DEO, it was thought that fewer side effects, especially dry mouth, would occur, thus improving patient compliance

[82]. Studies looking at salivary output showed markedly diminished production following administration of OXY IR or TOLT IR with gradual return to normal. In OXY ER group, salivary output was maintained at predose levels throughout the day [83]. OXY IR and ER have been compared in a multicenter, double-blind RCT of 106 patients, all of whom had previously responded to IR OXY [84]. Similar efficacy and similar side effect profiles were noted for both formulations.

As noted earlier in the OBJECT study, OXY 10 mg ER proved superior to TOLT 2 mg IR twice daily with respect to weekly UUI episodes, total incontinence, and frequency [53]. The two drugs were equally well tolerated. The follow-up OPERA study compared OXY 10 mg ER to TOLT 4 mg ER and found no significant difference in efficacy between the two drugs [54]. The incidence of dry mouth was statistically lower in the TOLT group. One general consensus following this study was that IR formulations of one drug should not be compared to ER formulations of another drug.

Three difference doses of OXY (5, 10, and 15 mg) were compared in a RCT, and a significant dose–response relationship for both UUI episodes and dry mouth was found. The greatest patient satisfaction was with the 15 mg dose [85].

Transdermal administration of OXY (OXY-TDS) alters the metabolism of the drug further reducing the production of DEO compared to OXY ER. The 3.9 mg daily dose patch decreased both micturition frequency and incontinence episodes, while increasing mean voided volume [86]. Dry mouth rate was similar to placebo. In a study comparing OXY-TDS to OXY IR, similar reductions in incontinence episodes were found, but significantly less dry mouth was seen with OXY-TDS (38% vs. 94% with OXY IR) [87]. In a third study, OXY-TDS was compared to placebo and TOLT ER [88]. Both drugs had similarly significant reduced daily incontinence episodes and increased voided volume, but TOLT ER was associated with a higher rate of adverse events. The major side effect for OXY-TDS was pruritus at the application site in 14% and erythema in 8.3%. The pharmacokinetics of OXY-TDS was studied using the blood and saliva samples in a two-way crossover RCT with OXY ER [89]. The TDS route of administration resulted in greater systemic availability of drug with minimal metabolism to DEO. As a result, patients had greater salivary output and less dry mouth than when taking OXY ER. However, in a review by Cartwright and Cardozo on the published and presented data, they concluded that the good balance between efficacy and tolerability with OXY-TDS was offset by the rate of local skin reaction [90]. In a study assessing the achievement of patient-selected goals of therapy, OXY-TDS demonstrated a significant improvement in daily urgency episodes with no difference in the achievement of patients' own goals for therapy or HRQL compared to placebo [302]. Intravesical administration of OXY is a conceptually attractive form of drug delivery, especially for patients who already perform CIC. A specific intravesical formulation of the drug is not available and currently the oral formulation, either liquid or crushed tablet in solution, is delivered by periodic insertion through a catheter. Several nonrandomized, unblinded, and nonplacebo-controlled studies have demonstrated efficacy of this therapy in a variety of patients with neurogenic bladders showing significant improvements in cystometric capacity, volume at first IVC, bladder compliance, and overall continence [91,92]. In a study looking at the pharmacokinetics of intravesical OXY versus oral, it was found that plasma OXY levels following oral administration rose to 7.3 mg/mL within 2 hours then precipitously dropped to <2 mg/mL at 4 hours [93]. In the intravesical group, plasma levels rose gradually to a peak of 6.2 mg/mL at 3.5 hours and remained between 3 and 4 mg/mL at 9 hours. From these data, it is unclear whether the intravesically applied drug acted locally or systemically.

In a double-blind RCT in 52 women with DO, patients received once-daily intravesical OXY (20 mg in 40 mL sterile water) or placebo for 12 days [94]. The results revealed significant differences in first desire to void (from 95 mL pretreatment to 150 mL posttreatment), cystometric capacity (205–310 mL), maximum pressure during filling (16–9 cmH_2O), daytime frequency (7.5–4), and nocturia (5.1–1.8). Side effects were similar in the treated and placebo groups. For unexplained reasons, 19/23 patients in the treated group continued to have symptomatic relief after termination of the study.

OXY topical gel is a transdermal formulation, which is applied once daily to the abdomen, thigh, shoulder, or upper arm area [95]. The 1 g application dose delivers approximately 4 mg of drug to the circulation with stable plasma concentrations. In a multicenter RCT, 789 patients (89% women) with urge predominant urinary incontinence were assigned to OXY gel or placebo once daily for 12 weeks. The mean number of UUI episodes, as recorded on a 3-day voiding diary, was reduced by 3.0 episodes/day versus 2.5 in the placebo arm ($p < 0.0001$). Urinary frequency was decreased by 2.7 episodes/day and voided volume was increased by 21 mL (vs. 2.0 episodes, $p = 0.0017$ and 3.8 mL, $p =$

0.0018 in the placebo group, respectively). Dry mouth was reported in 6.9% of the treatment group versus 2.8% of the placebo group. Skin reaction at the application site was reported in 5.4% of the treatment group versus 1.0% in the placebo arm. It is felt that improved skin tolerability of the gel over the OXY TDS delivery system is secondary to lack of adhesive and skin occlusion. The gel dries rapidly upon application and leaves no residue; person-to-person transference via skin contact is largely eliminated if clothing is worn over the application site. In a phase III study of 704 with urgency predominant urinary incontinence, OXY topical gel resulted in improvement in daily incontinence episodes, frequency of micturition, voided volume, and HRQL [338]. Dry mouth occurred in 7.4% vs. 2.8% of the placebo group ($p = 0.006$).

Propiverine

Propiverine is a musculotropic smooth muscle relaxant with nonselective antimuscarinic activity. Calcium antagonistic properties have also been found, but the importance of this component for the drug's clinical effects has not been established [96]. In an analysis of nine RCTs using propiverine in a total of 230 patients, a 17% reduction in micturition frequency was seen. Additionally, there was a 64 mL mean increase in bladder capacity and a 77% subjective improvement rate. Side effects were found in 14% [97]. In a study on patients with neurogenic DO, propiverine was found to increase bladder capacity and decrease maximum detrusor contractions compared to placebo [98]. Several comparative studies have confirmed the efficacy of propiverine and suggested that the drug may be equally efficacious in increasing bladder capacity and lowering bladder pressure with fewer side effects than OXY [99,100]. A study comparing propiverine 15 mg twice daily to TOLT IR 2 mg twice daily showed comparable efficacy, tolerability, and improvement in HRQL [101]. In 2006, Abrams and colleagues presented data that refuted these prior studies [102]. In a double-blind, placebo-controlled crossover study comparing propiverine 20 mg daily, propiverine 15 mg three times daily, OXY 5 mg three times daily, and placebo, propiverine 20 mg daily was inferior to OXY in reducing IVCs. Additionally, propiverine had a more pronounced effect on gastrointestinal, cardiovascular, and visual function.

A large Japanese study of 1584 patients randomized patients to solifenacin 5 or 10 mg, propiverine 20 mg, or placebo [103]. All active treatments showed superiority to placebo in reducing voiding frequency, increasing voided volume, and improving HRQL. Solifenacin 10 mg showed greater reduction in nocturia episodes and urgency episodes and increased volume voided compared to propiverine 20 mg. Side effects were also greater for the solifenacin 10 mg group with more dry mouth and constipation.

Antimuscarinic drugs are proven efficacious and safe and are the mainstays of treatment for OAB [15]. The continuous evolution and development of newer agents stems from the fact that the ideal agent has yet to be found—one that is LUT selective, easily administered, and relatively inexpensive. This search continues and therapies with different mechanisms of action are currently being studied with great promise. Until then, the lessons we have learned from comprehensive systematic review of the literature include the following [15]:

1. Older drugs such as OXY have high withdrawal rates due to side effects, while TOLT ER has consistently favorable tolerability.
2. Newer agents such as darifenacin, solifenacin, and fesoterodine provide dose flexibility to allow individual titration for maximal efficacy versus tolerability.
3. Once-daily dosing appears to be better tolerated and potentially more efficacious in improving symptoms and HRQL.

However, head-to-head studies comparing all of these agents are limited.

Three specific areas of concern with antimuscarinic medication deserve special mention: urinary retention, cognitive impairment, and glaucoma.

In the past, there was a universal concern regarding the risk of urinary retention when prescribing antimuscarinic drugs. However, as Andersson and Wein [11] and Andersson et al. [12] propose, these drugs are usually competitive antagonists that imply that when there is massive release of ACh during voiding, the effect of the drug should be diminished. If this did not occur, urinary retention would result from inability of the bladder to contract. And in fact, at high doses, urinary retention can occur but this is uncommon at the doses typically prescribed for DO [11]. Figure 46.2 illustrates our current understanding regarding the dose range used for beneficial effects in OAB/DO, and those needed to produce a significant reduction in the voiding contraction. Monitoring PVRs in patients with prostatic enlargement or incomplete bladder emptying is still recommended; however, these diagnoses should not be considered as absolute contraindications to the use of antimuscarinics.

More recently, a concern over the association of anticholinergics and cognitive impairment has prompted several studies evaluating reaction time, memory, confusion, and other cognitive decrements. In a longitudinal cohort study involving 372 adults age >60 years without dementia at recruitment, the effects of continuous anticholinergic drug use on cognition were assessed [104]. In this study, 80% of anticholinergic users were classified as having mild cognitive impairment compared with only 35% of nonusers. There was no difference between users and nonusers in the risk of developing dementia after 8 years of follow-up. Other studies in continent elderly volunteers have shown no significant effects on cognition [27].

Effects on voiding contraction
"Therapeutic window" for OAB
Concentration of antimuscarinic

Figure 46.2 Rationale for the use of antimuscarinics for treatment of OAB/DO. Blockade of muscarinic receptors at both detrusor and nondetrusor sites may prevent OAB symptoms and DO without depressing the contraction during voiding. Abbreviations: OAB, overactive bladder; DO, detrusor overactivity. (Adapted from Andersson K-E et al., Pharmacological treatment of urinary incontinence, in: Abrams P et al., eds., *Incontinence, 5th International Consultation on Incontinence*, ICUD-EAU, 2013, pp. 623–728.)

There are few data available on the cognitive consequences of anticholinergics in patients with dementia. However, cholinesterase inhibitors that are often used to improve cognition in Alzheimer's disease have been shown to precipitate urinary incontinence [105].

Patients with OAB and glaucoma present another therapeutic dilemma for urologists. Both conditions increase in prevalence with age, and it has been estimated that the conditions coexist in approximately 11.6% of female patients (in Japan) [106]. The distinction between open-angle and narrow-angle glaucoma is an important one, and when the answer is unknown, referral to an ophthalmologist is imperative. A Japanese study reported that in approximately 75% of the patients with glaucoma and OAB, the glaucoma is open angle, and this was felt to confer no additional risk to therapeutic intervention with anticholinergic medication. In the remaining 25% with narrow-angle glaucoma, the risk was felt to be elevated only if iridotomy has not been performed or has not successfully controlled the disease, reducing the true contraindication rate to approximately 8.3% of the patients with OAB. Interestingly, the same study found that 33% of the patients did not report glaucoma on their medical intake form. Underestimating the risk of glaucoma can result in blindness, albeit rarely, while overestimating (which often occurs out of fear) can result in denial of the most effective oral agents for the treatment of OAB. Complaints of eye pain, headache, or visual loss following initiation of anticholinergic therapy should be taken seriously and prompt medical advice should be sought [107].

Calcium Antagonists

Calcium channels and free intracellular calcium play a large role in excitation–contraction coupling in striated, cardiac, and smooth muscle [108]. Inhibitors of calcium channels have repeatedly been shown to inhibit bladder contraction in vitro [109], suggesting a possible role in the treatment of DO and incontinence; however, only limited clinical studies are available. Common side effects include headache, dizziness, flushing, and peripheral edema. These drugs are contraindicated in patients with poor cardiac conduction and those taking β-blockers [110].

Nifedipine

Nifedipine has been shown to be effective in inhibiting contraction in human and guinea pig bladder muscle [111]. It has also been shown to completely block the noncholinergic portion of contraction in the rabbit bladder [112]. These data suggest a potential role for nifedipine in controlling “atropine resistant” contractions, possibly in combination with an antimuscarinic agent. No clinical data are available to support this view.

Nimodipine

A double-blind, crossover RCT of 30 mg of nimodipine versus placebo in 86 patients with DO was performed [113]. There was no significant difference in the number of incontinent episodes or scores on validated questionnaires in those patients on treatment versus placebo.

Verapamil

Intravesical verapamil was compared to intravesical OXY, intravesical trospium, and placebo in 84 patients with urgency or UUI [114]. While OXY and trospium both significantly increased bladder capacity, decreased detrusor pressure, and decreased IVCs, verapamil did not.

There is no agent that will specifically block intracellular calcium release only in the bladder smooth muscle cells. Presently, there is no clinical evidence to support the use of calcium-channel inhibitors in the treatment of bladder dysfunction.

Potassium-Channel Openers

Similar to calcium channels, potassium channels also contribute to the membrane potential of smooth muscle cells and as a result affect smooth muscle tone. Potassium-channel openers relax various types of smooth muscle, including the detrusor, by increasing potassium efflux [79]. Several types of potassium-channel openers exist and at least two types, ATP dependant and big calcium activated, have been shown to induce bladder smooth muscle relaxation and reduce spontaneous contractions in human and other mammalian detrusor muscle [115]. Potassium-channel openers are not specific for the bladder, however, and are more potent in relaxing other tissues. In particular, potassium channels are expressed in vascular smooth muscle producing side effects on cardiovascular function, with potentially significant lowering of blood pressure [116]. Common side effects of this class of drug include headaches, flushing, reflex tachycardia, edema, angina, and hypertrichosis [117].

Cromakalim and Levcromakalim

Cromakalim was evaluated in 16 patients with refractory DO or neurogenic DO who had stopped other drug therapy due to intolerable side effects [118]. Of the 16 patients, 6 (38%) of them showed a decrease in micturition frequency and an increase in volume voided. Long-term observation was not possible because the drug was withdrawn from the market owing to reported adverse effects of high doses in animal toxicology studies.

Levcromakalim was administered intravenously to six patients with SCI and neurogenic DO [119]. An increase in the duration of detrusor contraction was seen but no other effects on urodynamic parameters were appreciated. A significant drop in blood pressure was seen precluding studies at a higher dose.

Pinacidil

Pinacidil is a potassium-channel opener that inhibits spontaneous myogenic contractions as well as contractile responses induced by electrical field stimulation and carbachol in isolated human detrusor [120]. A double-blind, crossover study in nine patients with DO and BOO failed to show any effects of pinacidil 25 mg daily on symptoms [121]. A significant decrease in standing blood pressure with stable heart rate was reported.

ZD0947

A double-blind, placebo-controlled, phase II study evaluated the efficacy and safety of ZD0947 at a dose of 25 mg daily for 12 weeks [122]. The results showed no improvement in voided volume, micturition frequency, or incontinence episodes.

Despite the promising preclinical efficacy data, presently potassium-channel openers are not a therapeutic option due to a lack of selectivity for the bladder over the cardiovascular tissues.

Prostaglandin and Cyclooxygenase Inhibitors

Prostaglandins (PGs) can be synthesized from the human bladder and released in response to different types of trauma [123]. They appear to cause contraction of the bladder muscle but it is unclear if PGs contribute to the pathogenesis of DO. Possible sensitization of sensory afferent nerves by PGs has been suggested by Andersson [79]. This would essentially increase the afferent input produced by a given degree of bladder filling contributing to the triggering of IVCs at a small bladder volume. Provided this theory is correct, PG synthesis inhibitors should decrease bladder contractility in response to various stimuli. However, clinical evidence for this is scant. Common side effects include hypertension, headache, diarrhea, dyspepsia, nausea, gastroesophageal reflux, and arthralgias. These drugs are contraindicated in renal impairment, advanced liver disease, and congestive heart failure and in the perioperative setting following coronary artery bypass surgery [124].

Flurbiprofen

Flurbiprofen is a PG synthesis inhibitor. A double-blind RCT evaluated the effects of flurbiprofen 50 mg three times daily in women with DO [125]. The results showed a favorable effect of the drug on delaying the intravesical pressure rise to a larger volume but did not abolish IVCs. There was a 43% incidence of side effects, primarily nausea, vomiting, headache, and gastrointestinal symptoms.

Indomethacin

A single-blind, crossover RCT in 32 patients with neurogenic DO compared indomethacin 50–100 mg daily to bromocriptine. Results showed symptomatic relief in daytime micturition frequency and nocturia in the indomethacin group. There were no urodynamic data reported. The incidence of side effects was high, occurring in 19 of 32 patients; no patients withdrew from the study.

Numerous PG synthesis inhibitors exist, most of which belong to the category of nonsteroidal anti-inflammatory drugs, but few have been studied in the treatment of DO. Despite the recent rage over cyclooxygenase inhibitors in many fields of medicine, no new RCTs in patients with DO have been published in the last decade.

β-Adrenergic Agonists

We have yet to prove whether the sympathetic nervous system plays an active role in filling/storage of the bladder in humans; however, the presence of β-adrenoceptors (AR) in human bladder muscle prompted many attempts to increase bladder capacity with β-adrenergic stimulation. Such stimulation can cause significant increases in the capacity of animal bladders that contain a moderate density of β-AR (1). In vitro studies show a strong dose-related relaxant effect of β_2-agonists on the bladder body of rabbits but little effect on the bladder base or proximal urethra. Receptor-binding studies suggest that the β-AR of the human detrusor is primarily of the β_2-subtype and favorable effects have been reported in patients with DO with the use of selective β_2-agonists [108,126]. More recently, the attention has turned to β_3-AR agonists after the real-time reverse transcriptase polymerase chain reaction data revealed a predominant expression of β_3-AR mRNA in human detrusor muscle [127]. In isolated human detrusor muscle, the selective β_3-agonists solabegron and mirabegron were both found to mediate muscle relaxation [130,131]. Facilitation of bladder storage with these agents is thought to be the result of both direct inhibition on the detrusor muscle and inhibition of sensory afferents from the bladder. β_3-AR agonists increase bladder capacity without altering voiding pressure or PVR urine volume [320]. Reported side effects include tachycardia, hypertension, headache, gastrointestinal effects, nervousness, palpitations, elevated serum glucose and lactate, and decreased serum potassium and calcium. These drugs are contraindicated in patients with uncontrolled hypertension and cardiac arrhythmias associated with tachycardia [128]. Overall, the side-effect profile is considered favorable compared to antimuscarinics and as a result has become a notable alternative agent for the treatment of OAB since its approval in the United States in June 2012.

Clenbuterol

Clenbuterol is a selective β_2-agonist. A double-blind, controlled study in women with UUI showed clenbuterol 0.01 mg three times daily had good therapeutic effect in 15 of the 20 patients [129]. This drug is not available in the United States.

Mirabegron

Mirabegron, a selective β_3-agonist, has been evaluated in human clinical trials and was approved in the United States in June 2012 for the treatment of OAB. The drug is rapidly absorbed after oral administration and 55% is excreted unchanged in the urine and 34% excreted unchanged in the feces. It is metabolized by the liver primarily by CYP3A4 and to a lesser degree by CYP2D6 [312]. Moderate renal impairment and mild hepatic impairment have little impact on drug metabolism and are not clinically important [308].

Mirabegron was evaluated in 262 patients with OAB in a phase IIA RCT versus TOLT 4 mg and placebo [132]. The treatment groups received either 100 or 150 mg twice daily and experienced a significant reduction in micturition frequency, incontinence episodes, and urgency symptoms, as well as an increase in volume voided. The drug was well tolerated in this study with the most common side effects being headache and gastrointestinal effects. A 5 beats per minute increase in pulse was noted in the 150 mg twice daily group. A phase IIB dose–response double-blind RCT was conducted using an ER form of mirabegron ranging from 25 to 200 mg once daily compared to TOLT 4 mg and placebo [304]. Dose-dependent improvements in micturition frequency and volume voided were noted. Discontinuation rates were very low ranging from 2.4% to 5.3%. The mean pulse rate increases in the 100 and 200 mg daily groups by 1.6 and 4.1 beats per minute, respectively. There was no increase in cardiovascular adverse events.

In a phase III, multicenter, double-blind RCT (n = 1328), patients with OAB were randomized to mirabegron 50 or 100 mg daily or placebo. After 12 weeks, both treatment groups demonstrated a statistically significant decrease in micturition frequency and incontinence episodes compared to placebo. The drug was well tolerated with similar rates of adverse events in the treatment and placebo groups.

In a similar European–Australian phase III study (n = 1978), patients with OAB were randomized to mirabegron 50 or 100 mg, TOLT 4 mg, or placebo [324]. Both doses of mirabegron achieved statistically significant improvement in urgency incontinence episodes and micturition frequency over placebo. The study was not appropriately powered to detect a statistical difference from TOLT but a numerical difference was noted. The incidence of hypertension and urinary tract infection (UTI) was identical in the two mirabegron and the placebo arm. The TOLT group has an increased incidence of dry mouth compared with placebo, and this was not observed with mirabegron. Post hoc subgroup analysis of this cohort was performed to assess the response to mirabegron in patients who had tried prior antimuscarinic agents [325]. Similar treatment benefit was noted in treatment-naïve patients and those who had discontinued prior antimuscarinic agents due to poor efficacy.

The safety and efficacy of mirabegron in the older population (age ≥65 and ≥75 years) were assessed with a prospective subanalysis of three phase III trials [351]. This study demonstrated that mirabegron 25 and 50 mg were effective in reducing urgency incontinence episodes and micturition frequency in this population and were well tolerated. A 1-year safety trial in this population demonstrated a sixfold higher incidence of dry mouth in the TOLT group than the mirabegron groups. Hypertension and UTI were the most common adverse effects of mirabegron. The drug was available in Japan several years before obtaining approval in the United States; the Japanese label contains a warning advising against the use of the drug in patients of reproductive age.

Terbutaline

Terbutaline, a β_2-agonist, has been reported to have a beneficial clinical effect at an oral dose of 5 mg three times a day [126]. In 15 patients evaluated, 12 became subjectively continent. Of the eight patients with documented urodynamic DO, six had stabilization of the detrusor on repeat evaluation. In nine patients, transient side effects including palpitations, tachycardia, or hand tremor occurred.

Antidepressants

Several antidepressants have been found to have beneficial effects in patients with OAB (1). These effects include facilitating urine storage by decreasing bladder contractility and increasing outlet resistance. In general, these agents have two major pharmacological actions. They have anticholinergic effects both centrally and peripherally, and they block the reuptake of serotonin and noradrenaline [133]. The most common side effect includes nausea, followed by dry mouth, dizziness, constipation, insomnia, and fatigue. Tricyclic antidepressants (TCAs) can have cardiotoxic side effects, as well as CNS effects including weakness, parkinsonian effects, fine tremor, manic or schizophrenic picture, and sedation [133]. The use of TCAs in conjunction with monoamine oxidase inhibitors is contraindicated. In general, the doses given for the treatment of DO are much lower than those prescribed for depression. Whether the same toxicity profile exists for these drugs at the lower dose remains to be seen.

Doxepin

Doxepin is a TCA that has been found to be more potent than other tricyclic compounds with respect to antimuscarinic and musculotropic relaxant activity [134]. In a double-blind, crossover RCT of women with IVCs and frequency, urgency, or UUI, it was found that this agent caused a significant decrease in nighttime frequency and incontinence episodes [135]. There was a near significant decrease in urine loss measured by pad weight and in cystometric parameters of first sensation and maximum bladder capacity. Doxepin treatment was preferred by 14 of the 19 patients, while 2 preferred placebo and 3 had no preference. During the treatment, 12 patients claimed they became continent.

Duloxetine

Duloxetine is a combined serotonin–norepinephrine reuptake inhibitor (SNRI), which has been shown to increase both bladder capacity and sphincteric muscle activity during filling and storage in the cat [136]. The data to support its role in increasing outlet resistance will be presented later. A RCT on 306 women with OAB looked at the effects of duloxetine 80 mg daily for 4 weeks, followed by 120 mg daily for 8 weeks [137]. The duloxetine group showed significant improvement in number of voids and incontinence episodes, voiding interval, and HRQL. No urodynamic indices showed improvement. The product information for this drug contains a black box warning due to increased suicidal thinking and behavior in those taking the drug for psychiatric disorders. Furthermore, the high withdrawal rate affecting 20%–40% of patients using the drug in short-term studies and up to 90% in long-term studies limits the potential clinical utility of this drug for the treatment of OAB [296].

Imipramine

Imipramine is a TCA that has been widely used clinically to treat DO despite a lack of good RCTs to document its effects. Imipramine has prominent systemic anticholinergic effects but only a weak antimuscarinic effect on bladder smooth muscle [138]. The effect of imipramine on noradrenaline reuptake is nonselective, and direct evidence suggesting it occurs in the LUT as well as the brain has been provided [139].

Clinically, imipramine seems to be effective in decreasing bladder contractility and increasing outlet resistance. In a study of elderly patients with DO, imipramine 25 mg nightly was given and increased by 25 mg every 3 days until either the patient was continent, the patient had side effects, or a dose of 150 mg was reached [140]. Of 10 patients, 6 became continent. In those patients who underwent repeated cystometry, bladder capacity increased by a mean of 105 mL and bladder pressure at capacity decreased by a mean of 18 cmH_2O. In our experience, the effects of imipramine on the LUT are often additive to those of antimuscarinic agents; however, it should be noted that the anticholinergic side effects may also be additive. A combination of low-dose imipramine and an antimuscarinic or an antispasmodic has been reported as useful for decreasing bladder contractility and detrusor pressure in some neurogenic patients [141]. However, serious toxic side effects can occur with therapeutic doses of imipramine, including orthostatic hypotension, ventricular arrhythmias, and prolongation of the QT interval. A proper risk–benefit analysis of imipramine in a good-quality clinical trial has not been performed.

Phosphodiesterase Inhibitors

PDE inhibitors were initially prescribed for the treatment of erectile dysfunction (ED) and found incidentally to improve LUT symptoms (LUTSs) in men [142]. LUT smooth muscle undergoes relaxation in the presence of cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) [143]. PDE inhibitors block the degradation of cAMP and cGMP resulting in greater intracellular concentrations. Side effects include headache, flushing, dyspepsia, vision changes, and myalgias. This class of drug is contraindicated in patients taking nitrates [34]. Tadalafil is the only PDE inhibitor approved for the treatment of LUTS and is specifically indicated in men with benign prostatic obstruction.

Sildenafil

A RCT evaluated the effects of sildenafil on ED and LUTSs in 189 men. Significant improvements in the International Prostate Symptom Score (IPSS) and HRQL were seen [144]. In the first RCT looking at sildenafil and voiding dysfunction in women, no significant differences were seen in patients with complete retention, partial retention, or obstructed voiding [145].

Tadalafil

A RCT comparing tadalafil to placebo in 281 men with ED and LUTSs produced clinically meaningful and significant symptomatic improvement in LUTS [146]. The drug was well tolerated with mild side effects.

Vardenafil

In another RCT, vardenafil 10 mg twice daily in men with ED and LUTS showed a significant improvement in IPSS and HRQL [147].

Vinpocetine

The PDE-1 inhibitor vinpocetine was evaluated in a multicenter, double-blind RCT in patients with urgency and UUI with urodynamically documented DO who failed the anticholinergic therapy [148]. The patients received either vinpocetine 20 mg three times daily or placebo. The results showed a significant reduction in micturition frequency in men; however, the remainder of assessed outcomes showed a trend toward improvement without reaching significance. The lack of side effects indicates that the dose delivered may have been too low. While large-scale studies in women using PDE inhibitors for DO have yet to be done, the early data in men suggest a possible role in the treatment of the bladder diseases. The mechanism of action to produce this beneficial effect in OAB remains unknown at this time. Few data are available regarding the use in women.

Botulinum Toxin

Botulinum toxin (BTX) is a neurotoxin produced by *Clostridium botulinum* and is a potent presynaptic inhibitor of ACh release at the neuromuscular junction of the muscle. In the bladder, cholinergic nerves play an important role in detrusor contraction and blockade of Ach is felt to play an essential role in decreasing DO in patients with OAB [321]. In addition to its effects on efferent pathways, BTX decreases the afferent sensory response of the bladder via inhibition of glutamate, substance P, and other neuropeptide release in the spinal cord [328]. Additional mechanisms of the effect of BTX on OAB symptoms may be explained by its ability to decrease expression of neurotrophic factors including nerve growth factor (NGF) and brain-derived neurotrophic factor in the bladder [335]. BTX is applied directly by cystoscopic injection into the detrusor muscle or suburothelial space producing a chemical denervation, which is reversible after approximately 6 months. Intravesical administration allows for high concentrations of the agent to reach the bladder tissue without systemic administration and resultant unsuitable levels in other organs. BTX does not cross the urothelium if instilled into the bladder and as a result injection cannot be avoided at this time [305]. BTX is considered second-line therapy in patients who are refractory to conventional oral antimuscarinic therapy or who do not tolerate it due to systemic side effects.

There are seven subtypes of BTX with subtype A (BTX-A) being the most relevant clinically. BTX-A is available under at least four different trade names, Botox® (onabotulinum toxin A), Dysport® (abobotulinum toxin A), Xeomin® (incobotulinum toxin A), and Prosigne®, and it has been found that these formulations are not equivalent. The vast majority of intravesical experience has been with

Botox®, with no bladder experience reported for Xeomin®. Botox® appears to be approximately three times more potent than Dysport® [149].

The dose and injection protocol for BTX has not been universally agreed upon and several variations exist. In the initial description, 300 units (U) of BTX-A was diluted in normal saline to a concentration of 10 U/mL. Under direct cystoscopic visualization using a 6F injection needle, 30 injections of 1 mL each were administered to the bladder wall in 30 different locations above the trigone [150]. Since that description, several other authors have described varying doses, dilutions, number of sites, and locations (trigone, suburothelial space) [151]. BTX has been approved for use in the United States at a dose of 200 U for the treatment of neurogenic DO and 100 U for the treatment of idiopathic OAB. This dose reduction was felt to appropriately balance the efficacy of treatment with risk of incomplete bladder emptying or urinary retention. There remains quite a bit of variability in dilution volume, injection volume, and number and location of injection sites.

Two phase III studies have been completed documenting the efficacy of 200 and 300 U of BTX on patients with neurogenic DO [306,314].

Cruz et al. reported a significant improvement in urinary incontinence episodes, quality of life, and urodynamic parameters in patients with multiple sclerosis (n = 154) and SCI (n = 121) treated with either 200 or 300 U of BTX compared to placebo [306]. There was no clinically relevant difference in the efficacy or duration of effect between 200 and 300 U, and the treatment was equally efficacious in patients with MS and SCI. The most frequent adverse effects reported were UTI and urinary retention, which were dose related. In patients who were not on CIC prior to BTX treatment, 30% of the 200 U groups and 42% of the 300 U group required initiation of CIC after treatment compared to 12% of the placebo group. The time to retreatment request was similar in both treatment groups (median 42.1 weeks).

Ginsberg et al. also reported a significant improvement in urinary incontinence episodes, quality of life, and urodynamic parameters in patients with multiple sclerosis (n = 227) and SCI (n = 189) treated with either 200 or 300 U of BTX compared to placebo [314]. This study also showed no clinically relevant difference in the efficacy or duration of effect between 200 and 300 U. In patients who were not on CIC prior to treatment, 35% of the 200 U group and 42% of the 300 U group required initiation of CIC after BTX treatment compared to 10% of the placebo group. Median time to retreatment request was similar for both treatment groups (36.4 weeks). Further studies are needed to assess the efficacy of 100 U in the neurogenic OAB population that voids spontaneously. Maintaining volitional voiding in the post-BTX injection phase may decrease the rate of postinjection UTI, although this is yet to be proven.

The onset of BTX-A effects is seen within the first 2 weeks after injection [152]. Urgency, nocturia, and frequency have been shown to improve as early as 2 days after BTX-A injection in neurogenic DO patients [153]. The reported duration of BTX-A following the first injection was 6–9 months [152] and duration of effect along with beneficial clinical effect after subsequent injections is maintained [154].

As clinicians and investigators gained experience and enthusiasm for BTX in neurogenic patients, the use for idiopathic OAB refractory to antimuscarinics was launched. In a double-blind RCT including 34 patients with idiopathic DO refractory to antimuscarinics, 200 U of BTX-A was studied [155]. Significant improvements in maximum cystometric capacity, frequency, and incontinence episodes were seen at 4 and 12 weeks. Despite clinical improvement, six patients (37.5%) required CIC to empty the bladder. In another RCT, 28 women with refractory idiopathic DO received BTX-A 200 U and 15 received placebo [156]. Approximately, 60% of the women who received BTX-A reported a clinical response with a mean duration of response of 373 days (compared to 62 days or less for placebo). PVR urine was increased in 43% of women in the treatment group and UTIs occurred in 75% of these women. The duration of retention following the first injection was approximately 2 months; however, following repeat injection, this duration increased to 5 months. In the largest study to date for idiopathic refractory OAB (n = 240 women), a double-blind, placebo-controlled trial of 200 U BTX versus placebo was conducted [347]. In this study, the 200 U of BTX was diluted in 20 mL of saline and injected in 1 mL aliquots in 20 bladder wall locations above the trigone. Significant reductions in voiding frequency (8.3 vs. 9.67, $p < 0.0001$), urgency episodes (3.83 vs. 6.33, $p < 0.0001$), leakage episodes (1.67 vs. 6.0, $p < 0.0001$), and incontinence rates (88% vs. 69%, $p = 0.002$) were noted at 6 months. UTI and initiation of CIC were more common after BTX injection, 31% vs. 11% and 16% vs. 4% ($p < 0.003$), respectively.

Given the degree of voiding dysfunction seen after BTX injection in patients with idiopathic DO, dose reduction studies looking at 100 U have been done. In a prospective, nonrandomized study including 100 men and women, 100 U of BTX-A was injected in 30 locations [157]. At 4 and 12 weeks follow-up, 88% of patients showed significant improvement in bladder function in regard to subjective symptoms, urodynamic parameters, and HRQL. There were four cases of urinary retention. Dmochowski et al. performed a large phase II, multicenter, dose-escalating RCT ($n = 313$) with BTX doses ranging from 50 to 300 U [309]. Doses of 100 U and greater were found to demonstrate durable efficacy with doses greater than 150 U contributing minimal additional benefit. Dose-dependent increases in PVR and the need for CIC were demonstrated. This study concluded that 100 U was the ideal dose to balance symptom relief and safety concerns for the treatment of refractory idiopathic OAB. Subanalysis of this study concluded that the presence of DO on baseline urodynamics was not necessary for successful treatment [337]. It was noted that clinical improvements and improvements in urodynamic parameters generally trended together.

BTX has also been compared to antimuscarinics in patients with nonrefractory idiopathic OAB [350]. This double-blind, placebo-controlled trial randomized women ($n = 249$) with urgency incontinence to anticholinergic therapy (solifenacin 5 mg, dose escalation to 10 mg or change to trospium XR 60 mg as needed) plus intradetrusor injection of saline or 100 U of intradetrusor BTX plus oral placebo. No difference was detected in reduction of urgency incontinence episodes between the two groups. Complete resolution of incontinence was significantly better in the BTX group (27% vs. 13%, $p = 0.003$). The anticholinergic group had a higher rate of dry mouth (46% vs. 31%, $p = 0.002$) but lower rates of catheter use (0% vs. 5%, $p = 0.01$) and less UTIs (13% vs. 33%, $p < 0.001$).

BTX in the elderly has been reported in 21 patients with a mean age of 81.2 years (range 75–92). One month after treatment with 200 U, 76% of patients reported greater than 50% improvement in symptoms. Mean duration of effect was 7.1 months. No treatment-related complications were reported.

Side effects of intravesical BTX include elevated PVR, urinary retention, and UTI [158].

BTX appears to be an effective addition to the armamentarium of therapies for the treatment of neurogenic and idiopathic OAB. Further studies are needed to determine optimum dosage, location, and methods of injection. The case for usage in patients with neurogenic OAB on CIC who leak between catheterizations seems clearer than in patients with idiopathic OAB or neurogenic OAB not on CIC, in whom the PVR issue has yet to be clarified.

Polysynaptic Inhibitors

Baclofen

Baclofen depresses synaptic excitation of motor neurons in the spinal cord and normalizes interneuron activity [159]. It has been found useful for the treatment of skeletal spasticity due to a variety of causes, and oral baclofen was tried in patients with idiopathic DO; however, its efficacy was poor likely due to the fact that it does not cross the blood–brain barrier [160]. Intrathecal baclofen has been shown to be useful in some patients with spasticity and bladder dysfunction [161]. All patients reported marked symptomatic improvement. Increases in bladder compliance and capacity were seen. Side effects of baclofen include drowsiness, vertigo, insomnia, weakness, ataxia, slurred speech, and psychiatric disturbances [162].

Other Potential Agents

Estrogen

The hormonally sensitive tissues of the bladder, urethra, and pelvic floor may play a role in voiding mechanisms. Noteworthy scientific work has been done looking at the effects of estrogen and its receptors on the LUT. Two types of estrogen receptors (α and β) have been identified in the trigone of the bladder, urethra, vagina, levator ani muscles, pelvic fascia, and the supporting ligaments [163]. In fact, all four layers of the urethra (epithelium, vasculature, connective tissue, and muscle) are estrogen sensitive and thought to play a role in maintaining positive urethral pressure. Menopause causes marked decline in the presence and expression of both α- and β-receptor subtypes. Epidemiological studies have implicated estrogen deficiency, as a result of menopause, in the etiology of voiding symptoms that occur as women age. However, the role of estrogen replacement for the treatment of LUTSs remains controversial.

It has been recognized that estrogen therapy has little effect in the management of SUI (this topic will be addressed further later) [164]. Estrogen may be of benefit in the treatment of irritative voiding symptoms including urgency, frequency, and UUI. It is unclear whether this is the effect of the drug on the reversal of urogenital atrophy or direct action on the LUT. One difficulty in interpreting the available conflicting data on the topic is the use of several difference estrogen preparations, doses, routes of administration and the inconsistent use of concomitant progesterone. There is good evidence that urogenital atrophy, both the symptoms and cytological changes, can be reversed by treatment with low-dose vaginal estrogen.

Estrogen is hypothesized to be able to affect LUTSs by several potential mechanisms including increasing urethral resistance, raising the sensory threshold of the bladder [165], and promoting relaxation of the bladder via the β_3-AR [166]. In the ovariectomized rabbit, estrogen replacement has been shown to decrease muscarinic receptor density thereby diminishing contractile response [167]. Estradiol has also been found to reduce the frequency and amplitude of rabbit spontaneous rhythmic detrusor contractions [168].

In the human clinical literature, conflicting data on the efficacy sustained release 17β-estradiol vaginal tablets for urgency and UUI exists. Cardozo et al. performed a RCT in 110 women with urgency, frequency, and UUI [169]. After 3 months of treatment, they were unable to show objective evidence of a reduction in urinary frequency or urgency. In a subset of patients with pretreatment urodynamic urgency without DO, visual analog scales posttreatment showed a reduction in urgency symptoms. The authors hypothesized that the symptomatic improvement in this group was likely related to the treatment of their urogenital atrophy. They concluded that “improvement in LUT pathology can not be expected unless it is due to estrogen deficiency.” A further RCT on 154 women using the same estrogen preparation showed a significant improvement in subjective frequency, urgency, and urge and SUI. No urodynamic assessment was performed in this study [170].

A systematic review of the effects of estrogen on OAB was performed by Cardozo et al. and identified 11 RCTs with 236 women receiving estrogen and 230 placebo controls [171]. Statistically, significant improvements in urinary frequency, urgency, number of incontinence episodes, first sensation to void, and bladder capacity were found for patients taking estrogen therapy. Separate analysis for systemic and locally applied estrogen revealed that local therapy, but not systemic, had a significant beneficial effect on all outcome variables. Systemic estrogen did have a beneficial impact on incontinence episodes and first sensation to void.

Major concerns about the use of estrogen must be addressed. Common adverse effects include anxiety, insomnia, irritability, mood disturbances, melasma, rash, pruritus, breast enlargement, breast pain, increase in high-density lipoprotein cholesterol and triglycerides, glucose intolerance, hot flashes, change in libido, dysmenorrhea, vaginal discharge, and arthralgias. Estrogen is contraindicated in women with hepatic dysfunction. Results of the Women’s Health Initiative (WHI) study clearly established a small but significant increase in the risk of breast cancer in estrogen–progestin combination therapy given for >3 years [172]. Unopposed estrogen in postmenopausal women increases the risk of endometrial carcinoma by 5–15-fold. However, coadministration with progestin eliminates this risk [172]. The Heart and Estrogen Replacement Study (HERS) together with the results of WHI unequivocally establish that the combination estrogen–progestin does not protect against coronary heart disease [172]. The risk of thromboembolic disease is clearly elevated in women taking oral estrogens with a history of preexisting cardiovascular disease [172].

The female LUT is greatly influenced by estrogen throughout life. The LUTSs that temporally coincide with menopause may or may not be the result of estrogen deficiency. Regardless, estrogen replacement has produced conflicting results in improving symptoms. Most authors believe that urogenital atrophy is the result of estrogen deficiency and responds well to estrogen replacement, especially locally. In some cases, irritative urological symptoms (usually in combination with vaginal symptoms) may result from atrophy and may respond to estrogen therapy [173]. At the current time, there is little evidence to support the primary use of estrogen therapy alone for the treatment of OAB symptoms. Further studies are needed to define its role as an adjuvant therapy in the treatment of OAB and perhaps provide a strong argument for primary use. Of great interest would be a study looking at the role of prophylactic estrogen versus that of therapeutic estrogen on LUTS development and progression.

Gabapentin

Gabapentin was originally designed as an anticonvulsant, but now has expanded indications for neuropathic pain, anxiety, and sleep disorders [174]. In a study of 16 patients with neurogenic DO, the efficacy of gabapentin was explored [175]. Results showed significant improvement in urodynamic parameters, particularly IVCs, and a reduction in irritative voiding symptoms. No adverse events were recorded. The authors hypothesized that DO may be controlled by modulating the afferent input from the bladder and the excitability of the sacral reflex center. In a second study of 31 patients with refractory OAB, 14 patients reported subjective improvement of their frequency [176]. Of these patients, 8 were still on the drug 1 year later with persistent efficacy. Adverse effects of gabapentin include somnolence, dizziness, ataxia, fatigue, diarrhea, tremor, and nystagmus [177]. Further studies that include a clarification of the recommended dosages are needed.

NK1-Receptor Antagonists (Aprepitant)

Tachykinins are a class of neuropeptides that includes substance P, neurokinin A, and neurokinin B, which function as sensory neurotransmitters. Their respective receptors, NK1, NK2, and NK3, are found in various areas of the brain and spinal cord and may play a role in DO [178]. NK1- and NK2-receptor antagonists were administered to rats undergoing awake cystometry and both a dose-dependent decrease in detrusor pressure and an increase in bladder capacity were seen [179]. A combination of the two drugs caused an additive effect. In animals with BOO, the antagonists produced urinary retention at a high rate. The authors concluded that NK1 and NK2 receptors may be involved in micturition control.

Aprepitant, an NK1-receptor antagonist used to treat nausea and vomiting in patients on chemotherapy, was found to improve OAB symptoms in a double-blind RCT of 125 postmenopausal women [180]. The drug significantly decreased micturition frequency and number of urgency episodes as reported on a 4–10-day voiding diary. Despite statistical significance, the clinical significance of these findings is questionable. With respect to micturition frequency, a reduction of 1.3 episodes/day was seen in the treatment group compared to 0.4 episodes/day in the placebo group. Urgency episodes were reduced by 1.8/day in the treatment group and 0.5/day in the placebo group. The mean number of UUI episodes and total urinary incontinence were also reduced in the treatment group (−1.5 vs. −1.1 and −1.5 vs. −1.2, respectively), although not significantly. Aprepitant was well tolerated in this study.

In a multicenter, double-blind RCT, 476 patients with OAB were randomized to the NK-1 receptor antagonist serlopitant (0.25, 1, or 4 mg/daily), TOLT 4 mg daily, or placebo [313]. Mean reduction in micturition episodes was significant for serlopitant 0.25 (−1.1) and 4 mg daily (−1.1), and for TOLT (−1.5) compared to placebo (−0.5), but not for serlopitant 1 mg (−0.8). A dose–response relationship was not demonstrated for serlopitant. TOLT was superior for most endpoints studied. Dry mouth was reported in 3.3% of those on serlopitant, 4.6% on placebo, and 8.8% on TOLT. The drug was well tolerated.

Side effects include fatigue, nausea, constipation, diarrhea, weakness, hiccups, hypotension, dizziness, dyspepsia, neutropenia, leucopenia, and proteinuria [181].

Tramadol

Tramadol is a widely prescribed analgesic that is centrally acting and has dual mechanisms of action [182]. The drug is a weak opioid receptor agonist but its metabolites are nearly as effective as morphine at the opioid receptor. Additionally, the drug and its metabolites inhibit serotonin and noradrenaline reuptake. This drug profile may be particularly useful in the treatment of DO as shown in a RCT with duloxetine [137]. Animal studies have shown that tramadol abolishes experimentally induced DO [183]. In a double-blind RCT of 76 patients with idiopathic DO, tramadol 100 mg twice daily caused significant reduction in frequency and number of incontinence episodes [184]. Urodynamic parameters also showed improvement. Side effects of this drug include flushing, dizziness, headache, insomnia, somnolence, pruritus, constipation, nausea, vomiting, dyspepsia, hot flashes, diaphoresis, and weakness [185].

Increasing Bladder Capacity/Decreasing Sensory Input

Vanilloids

Relatively recently, the concept of blocking afferent nerves as a mechanism for controlling the micturition reflex has gained momentum as a potential therapeutic target in the treatment of OAB.

Afferent blockade would, at least in theory, be more desirable since it would block the micturition reflex rather than blocking the contraction of the detrusor.

There appears to be an upregulation of C-fiber afferent neurons in the bladders of patients with SCI [186] and chronic BOO [187] and those with idiopathic DO [188]. It has also been found that these upregulated C-fibers, in the bladders of patients with neurogenic DO, have increased expression of the vanilloid receptor, transient receptor potential vanilloid-1 (TRPV1) [189]. This receptor naturally responds to noxious stimuli including acidic pH, high temperatures, and spicy peppers [190]. A number of vanilloids, most notably capsaicin and resiniferatoxin (RTX), can also bind to this receptor creating an inhibitory effect. Side effects of these drugs tend to be local in nature and may include transient burning and stinging, elevated PVR, urinary retention, and UTIs.

BTX

As mentioned earlier, BTX produces a muscular paralysis in the bladder that improves DO. Additionally, BTX-A may decrease levels of neurotrophic agents in the bladder decreasing visceral afferent nerve transmission. NGF, one of these agents, is important in sensory nerve growth, maintenance, and plasticity. Generally, patients with neurogenic DO are found to produce greater levels of NGF in the bladder than controls. A significant decrease in NGF can be detected after intravesical administration of BTX pointing to another possible mechanism whereby BTX acts on the bladder [191].

Capsaicin

Capsaicin binds to TRPV1 and causes depolarization and excitation of sensory nerve fibers followed by a refractory period. Repeated or high-dose exposure causes desensitization, inactivating the nerve terminal. Systemic and topical capsaicin produce a reversible antinociceptive and anti-inflammatory action after an initially undesirable analgesic effect [192]. In a noncontrolled study of six patients, intravesical instillation of capsaicin (0.1–10 μM) produced a dose-related reduction in first desire to void, bladder capacity, and voiding pressure [193]. Five patients reported marked attenuation of symptoms beginning 2–3 days after instillation and lasting for 4–16 days; after that time, the symptoms gradually reappeared but were no worse. During instillation, patients reported a warm burning sensation in the suprapubic area that was felt in the urethra during voiding. Fowler and colleagues [194] reported considerably higher doses (1 or 2 mmol/L) in 12 patients with SCI and intractable urinary incontinence and two patients with idiopathic DO. Nine patients showed improvement in bladder function lasting for between 3 weeks and 6 months. Urodynamics revealed an increase in bladder capacity and a decrease in maximum detrusor pressure. There were no reported complications. In a larger study on 79 patients with 5-year follow-up, De Ridder and colleagues found intravesical administration of 1–2 mmol/L of capsaicin produced, complete continence in 44% of patients, satisfactory improvement in 36%, and failure in 20% [195]. Clinical benefit from single instillation lasted 3–6 months. Other studies have shown no beneficial effects of capsaicin with marked reactive changes of the urothelium [196]. Only one RCT has compared capsaicin to 30% ethanol, the vehicle solution [197]. The 10 patients randomized to capsaicin had significant decreases in voiding frequency, urinary leakage, and maximum detrusor pressure and significant increase in cystometric capacity. These changes were not seen in the control group who received the vehicle, 30% ethanol. Side effects consisted primarily of instillation triggered suprapubic pain, urgency, hematuria, and autonomic dysreflexia and were seen in seven patients from each group. The authors concluded that the side effects of capsaicin are attributable to the vehicle. Further studies by the same group showed that 1 mmol/L capsaicin diluted in glucidic solvent produced favorable and similar results as RTX 100 nMol/L diluted in 10% ethanol [198]. Neither group experienced significant side effects and the tolerance of the new capsaicin solvent was excellent.

Resiniferatoxin

RTX is an analog of capsaicin that is approximately 1000 times more potent for desensitization, but much less potent for excitation [199]. Several small, open-label studies showed beneficial effects of RTX with reduction in micturition frequency and incontinence episodes [198]. In a double-blind, placebo- controlled trial of RTX in 28 patients with neurogenic DO, a significant decrease in micturition frequency and incontinence episodes and an increase in bladder capacity were seen [200]. In a study comparing RTX to BTX-A in patients with neurogenic DO, both neurotoxins improved bladder capacity and reduced the number of incontinence episodes [201]. BTX-A, however, was considered more effective. In 54 patients with idiopathic DO, a RCT showed RTX is effective in improving incontinence [202]. Rios and colleagues, however, were unable to replicate those results in their RCT of 58 patients with idiopathic DO [203]. They showed no significant difference between a single dose of RTX 50 nM and placebo. The variability in clinical results may stem from the fact that different origins of RTX and different preparation techniques may cause substantial differences in the amount of drug actually delivered.

Overall, intravesical capsaicin and RTX may be promising therapy for DO and possibly sensory dysfunction of the LUT; however, many problems exist. Optimal dosage, method, and timing of delivery, as well as delivery vehicle, remain unclear. TRPV1 antagonists that block rather than desensitize the receptor are entering preliminary clinical trials.

Increasing Outlet Resistance

As mentioned earlier, decreased outlet resistance may manifest from damage to the smooth or striated sphincter secondary to surgical, obstetric, or other mechanical trauma, or degeneration of innervation with loss of neuronal mass secondary to neurological disease, aging, or trauma [4]. In addition, in women it may result from decreased pelvic floor support of the bladder outlet. Clinically, this manifests as effort related or SUI or, when severe, as complete gravitational incontinence. Treatment is aimed at increasing outlet resistance. Outlet resistance, at least as reflected by urethral pressure measurements, does not seem to be clinically affected by anticholinergic therapy.

Alpha-Adrenergic Agonists

The bladder neck and proximal urethra contain a preponderance of α-adrenergic receptor sites, which, when stimulated, produce smooth muscle contraction and an increase in maximal urethral pressure (MUP) and maximal urethral closure pressure (MUCP) [1]. The urethral rhabdosphincter, which is made up of striated muscle, is innervated by Onuf's nucleus and responds to noradrenaline via α1-AR receptor-dependent depolarization [353]. α-Adrenergic stimulation generally increase outlet resistance to a variable degree but are most often limited by their potential side effects including blood pressure elevation, anxiety, insomnia, headache, tremor, weakness, palpitations, cardiac arrhythmia, and respiratory difficulties. These agents should be used with caution in patients with hypertension, cardiovascular disease, and hyperthyroidism [204].

Ephedrine

The use of ephedrine to treat SUI was mentioned as early as 1948 [204]. This is a noncatecholamine sympathomimetic agent that enhances release of noradrenaline from sympathetic neurons and directly stimulates both α- and β-ARs. The oral adult dosage is 25–50 mg four times daily [205]. In 38 patients with sphincteric incontinence treated with ephedrine sulfate, 27 reported "good-to-excellent" results. The beneficial effects were most often achieved in those with minimal to moderate incontinence symptoms; little benefit was achieved in patients with severe SUI [205].

Midodrine

Midodrine is a long-acting α-adrenergic agonist reported to be useful in the treatment of seminal emission and ejaculation disorders following retroperitoneal lymphadenectomy. Treatment with 5 mg twice a day for 4 weeks in 20 patients with SUI produced a cure in 1 and improvement in 14. The MUCP rose by 8.3% and the planometric index of the continence area on profilometry increased by 9% [206].

Norfenefrine

Norfenefrine is an α-agonist given as a slow-release tablet. In a study on 20 women with SUI treated with norfenefrine, 19 reported reduced urinary leakage with 10 reporting resolution of their incontinence [207]. MUCP increased in 16 patients during treatment, the mean rise being 53–64 cmH_2O. Another study randomized 44 patients with SUI to treatment with norfenefrine (15–30 mg three times daily) or placebo for 6 weeks duration. Subjective improvement was reported in 12/23 (52%) of the treatment group versus 7/21 (33%) of the placebo group; this difference was not statistically significant. Judged by a stress test, seven patients in each group became continent with

11/23 (48%) of the treatment group improving both subjectively and objectively compared to 5/21 (24%) of the placebo group ($p = 0.09$).

Phenylpropanolamine

Phenylpropanolamine (PPA) shares the pharmacological properties of ephedrine and is approximately equal in peripheral potency while causing less central stimulation. It was available in 25 or 50 mg tablets and 75 mg timed-release capsules and was a component of numerous proprietary mixtures marketed for the treatment of nasal and sinus congestion and appetite suppression [208]. After a report that the risk of hemorrhagic stroke was 16 times greater in women <50 years of age who had been taking PPA as an appetite suppressant and three times higher in women who had been taking the drug for <24 hours as a cold remedy, PPA was removed from the market in the United States [209].

Pseudoephedrine

Pseudoephedrine, a stereoisomer of ephedrine, is used for similar indications and carries similar precautions. The adult dosage is 30–60 mg four times a day, and the 30 mg dose is available in the United States without prescription.

A recent Cochrane review evaluated randomized and quasi-RCTs in adults with SUI treated in at least one arm of the trial with an adrenergic agonist drug [210]. The number of eligible trials that were identified involving 1099 women is 22 (there were no controlled trials reporting on the use of these drugs in men). The authors concluded, “there was weak evidence to suggest that use of an adrenergic agonist was better than placebo treatment.” They also reported a similar adverse events profile for adrenergic agonists and placebo.

α_2-*AR Antagonists*

Early data in rats following spinal cord transaction suggest a potential role for α_2-antagonists in the treatment of SUI [211]. Potential mechanisms of action include CNS inhibition of the release of glutamate, an excitatory neurotransmitter released at nerve terminals to modulate the continence reflex in response to increases in intra-abdominal pressure. Essentially, α_2-antagonists may add to striated sphincter activity by inhibiting an inhibitory action on Onuf’s nucleus.

β-*Adrenergic Antagonists and Agonists*

Theoretically, β-adrenergic antagonists might be expected to “unmask” or potentiate α-adrenergic effect, thereby increasing urethral resistance. The opposite effect may be expected with β-adrenergic agonists with a decrease in urethral pressure, but β-agonists have been reported to increase the contractility of fast-contracting striated muscle fibers and suppress slow-contracting fibers [212].

Clenbuterol

Clenbuterol, a selective β_2-agonist, has been reported to potentiate field stimulation–induced contraction of periurethral muscle from the rabbit. This study led to speculation on the drugs ability to treat sphincteric incontinence and in fact, increased urethral pressures were seen with the clinical use of clenbuterol [213]. In a RCT comparing clenbuterol to pelvic floor exercises or combined therapy in 61 patients with SUI, the efficacy from the drug alone was 76.9% versus 52.6% in the exercise group and 89.5% in the combined group [214]. Further work is needed to adequately assess the effects of this drug on SUI. This drug is not available in the United States. Side effects include headache, muscle tremor, insomnia, sweating, increased appetite, palpitations, hypertension, anxiety, and hyperglycemia [215].

Propranolol

Propranolol, a β-antagonist, has been reported to have beneficial effects in the treatment of SUI; however, no RCTs have been performed for this indication. In one study, a dose of 10 mg four times daily (a relatively small dose) was found to be effective, but these results became manifest only after 4–10 weeks of treatment [216]. This is a difficult phenomenon to explain as cardiac effects of the drug occur rather promptly. Potential side effects, including heart failure and increased airway resistance, have limited its acceptance as a therapeutic agent for SUI. Side effects include bradycardia, hypotension, confusion, depression, dizziness, fatigue, lethargy, insomnia, bronchospasm, constipation, and diarrhea. Propranolol is contraindicated in patients with uncompensated congestive heart failure, severe heart block, and severe asthma or chronic obstructive pulmonary disease [217].

Antidepressants

Duloxetine

Duloxetine, as mentioned earlier, is a combined SNRI FDA approved in the United States for depression, diabetic neuropathic pain, and generalized anxiety disorder and licensed in the European Union for the treatment of SUI. It has been shown to increase sphincteric muscle activity during the filling/storage phase of micturition with no effect on sphincter function during voiding in a cat model of irritated bladder [218]. Duloxetine exerts its effects on serotonin and norepinephrine nerve terminals by prevention of reuptake [346]. These nerve terminals are dense in spinal areas associated with LUT function (pudendal nerve and Onuf's nucleus) and activation leads to rhabdosphincter contraction. The innervation of the rhabdosphincter is felt to be distinct from the innervation of the surrounding levator ani muscles [345]. It has also been noted that duloxetine increased bladder capacity, as noted earlier, probably through a CNS effect. The effects on the sphincter were reversed by α_1-adrenergic and $5HT_2$-serotonergic antagonism, while the effects on the bladder were provoked by serotonin and noradrenaline in the synaptic cleft. Duloxetine is lipophilic, well absorbed, and extensively metabolized [219].

There have been several RCTs documenting the effects of duloxetine in the treatment of SUI. Dmochowski and colleagues enrolled 683 patients in a double-blind RCT comparing duloxetine 40 mg twice daily to placebo [220]. There was a 50% decrease in incontinence episodes in the duloxetine group compared to 27% in the placebo group; a significant improvement in HRQL was also seen in the duloxetine group. The improvements with duloxetine were associated with significant increases in the voiding interval (20 min vs. 2 min) compared to placebo. The discontinuation rate was higher in the duloxetine group (24%) than placebo (4%), most frequently due to nausea, which was usually transient.

A Cochrane review of the effects of duloxetine on SUI summarizes data from nine RCTs totaling 3060 women [221]. Cure rate in the duloxetine 40 mg twice daily group was higher than in the placebo group (10.8% vs. 7.7%, $p = 0.04$). Significant reductions in incontinence episodes and improvement in HRQL and patient global impression of improvement were seen. However, no data were available on sustainability of treatment. The estimated absolute size of effect showed that for every 100 patients treated, three patients were cured. Only one trial reported objective cure data and showed no clear difference between drug and placebo. Adverse events were common (71% vs. 59% in placebo) but were not considered serious. Nausea was the most common complaint and the incidence ranged from 23% to 25% and was the main reason for discontinuation. Other side effects reported were vomiting, constipation, dry mouth, fatigue, dizziness, and insomnia. Across these six trials, 17% in the drug group withdrew versus 4% in the placebo arm. The authors conclude that more research is needed to determine whether duloxetine is clinically effective and cost effective compared to the other minimally invasive or more invasive treatment options available.

More recently, Bent et al. evaluated the effect of duloxetine 40 mg twice daily versus placebo in 588 women with mixed urinary incontinence [298]. They found a significant reduction in both urgency incontinence episodes (58% vs. 40%, $p < 0.001$) and stress incontinence episodes (59% vs. 43%, $p < 0.001$) compared to placebo. Significant improvements were also reported in quality-of-life scores and patient impression of improvement. Nausea (18% vs. 4.5%), dry mouth (12% vs. 2.8%), dizziness (9.7% vs. 2.4%), constipation (8.3% vs. 4.2%), and fatigue (6.7% vs. 2.8%) were the primary adverse effects.

Schagen van Leeuwen et al. evaluated the safety and efficacy of duloxetine in a RCT involving 265 elderly women (≥65 years) with SUI or stress predominant mixed incontinence [340]. They found a significantly greater reduction in incontinence episodes compared to placebo (−52.47% vs. 36.7%, $p < 0.001$). Secondary outcomes including pad use, mean time between voids, quality of life, and global impressions of improvement were all significantly improved compared to placebo. Adverse drug effects include dry mouth, fatigue, constipation, and hyperhidrosis were significantly more common in women taking duloxetine.

Persistence on therapy was studied and found to be quite low with only 31% of the originally 228 patients enrolled still on therapy beyond 4 weeks [349]. At 6 months, only 10% remained on therapy, which remained stable at 9% at 1 year. More than half of participants reported side effects as the reason for discontinuation and 33% reported lack of efficacy. One year after enrollment, 82% of the original cohort elected to undergo a midurethral sling procedure for treatment of their stress incontinence. In a study assessing the maintenance of efficacy of duloxetine, Bump et al. reported persistence on therapy at 1 year to be 42.5% of a cohort of 1424 [301]. Of those who continued, >80% reported they were at least "better since starting treatment" based on the Patient Global Impression of Improvement measure. In the same manuscript, a separate cohort of 2758 patients reported a median reduction in incontinence episodes of 50%–77% and a Patient Global Impression of Improvement of at least "better" in 70%–88%, both of which remained stable over 72 weeks of therapy.

Where duloxetine fits in the treatment algorithm for SUI is likely as a second-line agent for women unable or unwilling to undergo surgery as suggested by Shaban [342] and Robinson [336].

There is a "black box" warning of "increased risk of suicidal thinking and behavior in children, adolescents, and young adults taking antidepressants for major depressive disorder and other psychiatric disorders" [311]. Other warnings include risk for hepatotoxicity in patients with substantial alcohol use or chronic liver disease, orthostatic hypotension, serotonin syndrome, withdrawal symptoms with abrupt discontinuation, and increase concentration of drug with inhibitors of CYP1A2 and CYP2D6. The most common adverse effects compared to placebo are nausea (24% vs. 8%), dry mouth (13% vs. 5%), fatigue (10% vs. 5%), somnolence (10% vs. 3%), insomnia (10% vs. 6%), constipation (10% vs. 4%), and dizziness (10% vs. 5%) [311,342].

Imipramine

The actions of imipramine have been discussed in further detail earlier. On a theoretical basis, an increase in urethral resistance might be expected if an enhanced α-adrenergic effect at this level resulted from an inhibition of noradrenaline reuptake. However, imipramine also causes α-adrenergic blocking effects, at least in vascular smooth muscle. Many clinicians have noted improvement in patients treated with imipramine primarily for DO but who had in addition some component of sphincteric incontinence. In a study of 30 women with SUI who were treated with imipramine 75 mg daily for 4 weeks, 21 women reported continence; the mean MUCP for the group increased from 34.06 to 48.23 cmH_2O [222]. There are no RCTs on the use of imipramine for SUI. The safety issues (see pp. 428–429) are potentially significant. Adverse effects are listed in pp. 428–429.

Estrogens

Although estrogens have been recommended for the treatment of incontinence for many years, there remains considerable controversy over the risk/benefit ratio for this purpose. Numerous clinical studies exist; however, little consistency in the methodology or delivered drug makes interpretation of the available data problematic. As mentioned in the section earlier on estrogen treatment for OAB, menopause causes marked decline in the presence and expression of both α- and β-estrogen receptor subtypes. After menopause, urethral pressure parameters normally decrease slightly, and although this change is generally conceded to be related in some way to decreased estrogen levels, it is still largely a matter of speculation whether the actual changes occur in the smooth muscle, blood circulation, supporting tissues, or mucosal seal mechanism [223].

Two meta-analyses have shed some light on the use of estrogen therapy in the treatment of SUI. The Hormones and Urogenital Therapy Committee reviewed 166 articles containing 6 controlled and 17 uncontrolled trials [165]. They were able to show subjective improvement in urinary continence, but when objective urine loss was measured, there was no significant change. Only one study showed an increase in MUCP. In the second meta-analysis, the authors concluded that "published trials do not support estrogen replacement as efficacious therapy for SUI" [224].

In an open comparative crossover RCT in 20 postmenopausal women with SUI, both vaginal estriol suppositories 1 mg daily and oral PPA 50 mg twice daily increased the MUCP and the continence area on profilometry [225]. PPA was clinically more effective than estriol but not sufficiently so to obtain complete continence. With combined therapy, eight patients became completely continent, nine were considerably improved, and only one remained unchanged. Two patients dropped out of the study because of side effects. PPA is no longer on the market, but this study suggests estrogen may have a role in combination therapy with α-agonists.

Secondary analysis of 1525 participants of HERS who were randomly assigned to hormone therapy (n = 768) or placebo (n = 757) revealed greater worsening of incontinence symptoms in the treatment group (39% vs. 27%, $p < 0.001$). Review of the data from the WHI study on 23,296 postmenopausal women revealed that after 1 year of use hormone therapy increased all types of urinary incontinence, with SUI being the most common [226].

These women were randomized based on hysterectomy status to estrogen alone, estrogen plus progesterone, or placebo. Estrogen alone, or in combination with progesterone, was shown to increase the risk of incontinence among continent women and worsen incontinence in mildly symptomatic women.

A review article by Cardozo concluded that there is no convincing evidence that estrogen improves SUI; however, there is a suggestion that vaginal estrogen alleviates urgency, UUI, frequency, nocturia, and dysuria [227]. Vaginal estrogen is thought to exert this positive effect via improvement in cytological changes secondary to urogenital atrophy [228].

The debate over the use of estrogen runs much deeper than its potential effects on the urinary tract. Impact on cardiovascular disease, osteoporosis, vasomotor symptoms, breast cancer, and other conditions must factor into the risk–benefit analysis. Adverse effects are listed in pp. 430–431.

FACILITATION OF BLADDER EMPTYING

Absolute or relative failure to empty the bladder results from decreased bladder contractility, increased outlet resistance, or both [2]. Failure of adequate bladder contractility may result from temporary or permanent alterations in any one of the neuromuscular mechanisms necessary for initiating and maintaining a normal detrusor contraction. In a neurologically normal individual, inhibition of the micturition reflex may be secondary to painful stimuli, especially stimuli from the pelvic and perineal areas, or it may be psychogenic. Some drug therapies may inhibit bladder contractility through neurological or myogenic mechanisms. Bladder smooth muscle function may be impaired from over distension, severe infection, or fibrosis. Increased outlet resistance is generally secondary to anatomic obstruction but may be secondary to a failure of coordination of smooth or striated sphincter during bladder contraction. The treatment of failure to empty consists of attempts to increase intravesical pressure, to facilitate the micturition reflex, or to decrease outlet resistance—or some combination of the aforementioned treatment.

Facilitating Bladder Contraction

Parasympathomimetic Agents

Because a major portion of the final common pathway in physiological bladder contraction is the stimulation of parasympathetic postganglionic muscarinic cholinergic receptor sites, agents that imitate the actions of ACh might be expected to be effective in treating patients who cannot empty their bladder because of inadequate bladder contractility. ACh itself cannot be used for therapeutic purposes because of its actions at central and ganglionic levels and because of its rapid hydrolysis by acetylcholinesterases and butyrylcholinesterases [229].

Bethanechol Chloride

Many ACh-like drugs exist, but only bethanechol chloride (BC) has a relatively selective action in vitro on the urinary bladder and gut, with little or no nicotinic action [230]. In vitro, BC causes a contraction of smooth muscle from all areas of the bladder [231]. For more than 60 years, BC has been recommended for the treatment of the atonic or hypotonic bladder and it has been reported to be effective in achieving "rehabilitation" or the chronically atonic or hypotonic detrusor [232]. When so used, it is recommended that the drug be initially administered subcutaneously in a dose of 5–10 mg every 4–6 hours, along with an intermittent bladder decompression regimen. The patient is asked to try to void 20–30 minutes after each dose. When the residual urine volume has decreased to an acceptable level, the dose is gradually decreased and ultimately changed to an oral dose of 50 mg four times daily. In cases of partial bladder emptying, a therapeutic trial with an oral dose of 25–100 mg four times daily may be utilized in conjunction with attempted voiding every 4 hours. BC has also been used to stimulate or facilitate the development of reflex bladder contractions in patients with spinal shock secondary to suprasacral SCI [233].

Although anecdotal success in using BC in patients with voiding dysfunction is reported, there is little or no evidence to support its success in facilitating bladder emptying in series of patients in which the drug was the only variable [234]. Short-term studies in which the drug was the only variable have generally failed to demonstrate significant efficacy in terms of urine flow and PVR [235]. In a double-blind RCT that looked at the effects of two catheter-management protocols and the effect of BC on postoperative urinary retention following gynecological urinary incontinence surgery, BC was not at all helpful [236]. In a 2010 Cochrane systematic review, no statistically significant association between successful outcome and use of cholinergic agents was reported in the setting of postoperative retention [300]. When cholinergic agents were combined with sedatives, an improved likelihood of spontaneous voiding was noted compared to placebo (RR 1.39, 95% CI 1.07–1.82).

Although BC is capable of eliciting an increase in bladder smooth muscle tension, as would be expected from studies in vitro, its ability to stimulate or facilitate a coordinated and sustained physiological bladder contraction in patients with voiding dysfunction has been unimpressive [234]. Furthermore, it has been shown that bethanechol exerts its effects on intact smooth muscle cells only and therefore idiopathic detrusor atony is poorly responsive to therapy [297,300,333]. However, due to the paucity of pharmacotherapy to improve bladder emptying, many clinicians continue to use BC in the hope of improving emptying as long as the medication is tolerated without adverse effects by the patient or is contraindicated. The potential side effects of cholinomimetic drugs include flushing, nausea, vomiting, diarrhea, gastrointestinal cramps, bronchospasm, headache, salivation, sweating, and difficulty with visual accommodation [230]. Intramuscular and intravenous use can precipitate acute and severe side effects, resulting in acute circulatory failure and cardiac arrest, and is therefore prohibited.

PGs

The reported use of PGs to facilitate emptying is based on the hypothesis that these substances contribute to the maintenance of bladder tone and bladder contractile activity [108]. PGE_2 and $PGF_2\alpha$ cause bladder contractile responses in vitro and in vivo. PGE_2 seems to cause a net decrease in urethral smooth muscle tone; $PGF_2\alpha$ causes an increase. The most common side effect reported with PG therapy is diarrhea [237].

PGE_2

Instillation of 0.5 mg PGE_2 into the bladders of 22 women with varying degrees of urinary retention resulted in acute emptying and an improvement in long-term emptying over several months in two-thirds of the patients studied [238]. In general, a decrease in the volume at which voiding was initiated, an increase in bladder pressure, and a decrease in PVR were seen. Another studied looked at the intravesical use of 1.5 mg of PGE_2 (diluted with 20 mL 0.2% neomycin solution) in patients whose bladder exhibited no contractile activity or in whom bladder contractility was relatively impaired [239]. Of 36 patients, 20 showed a strongly positive response and six showed a weakly positive response; 14 patients were reported to show prolonged beneficial effects. The authors noted that the effects of PGE_2 appeared to be additive or synergistic with cholinergic stimulation in some patients. Other studies have reported no effect of PGE_2 on urinary retention [240], with other suggesting instigation of urinary urgency, reduced bladder capacity, and bladder instability with intravesical PGE_2 [241].

$PGF_2\alpha$

Intravesical instillation of 7.5 mg $PGF_2\alpha$ produced reflex voiding in some patients with incomplete suprasacral SCI [242].

The favorable response to a single dose of drug, when present, lasted from 1 to 2.5 months. In women undergoing hysterectomy, 16 mg of $PGF_2\alpha$ in 40 mL of saline given intravesically reduced the frequency of urinary retention compared to saline instillation alone [243]. The same treatment protocol given to women undergoing other vaginal procedures did not yield these results. Daily intravesical doses of $PGF_2\alpha$ and intravaginal PGE_2 reduced the number of days required for catheterization after SUI surgery compared with a control group receiving intravesical saline [244]. Other investigators, however, have reported conflicting or negative results [240].

PGs have a relatively short half-life, and it is difficult to understand how any effects after a single application can last as long as several months. If such an effect does occur, it must be the result of a "triggering effect" on some as yet unknown physiological or metabolic mechanism. Because of the number of conflicting positive and negative reports with various intravesical preparations, double-blind RCTs would be helpful to determine whether there are circumstances in which PG usage can reproducibly facilitate emptying or treat postoperative retention. In a 2010 Cochrane systematic review, intravesical PG was noted to significantly improve spontaneous voiding in the setting of postoperative urinary retention (RR 3.07, 95% CI 1.22–7.72) [300].

α-Adrenergic Blockers

Studies in cats have demonstrated a sympathetic reflex during bladder filling that promotes urine storage partly by exerting an α-adrenergic inhibitory effect on pelvic parasympathetic ganglionic transmission [245]. Some investigators have suggested that α-adrenergic blockage, in addition to decreasing outlet resistance, may facilitate transmission through these ganglia and thereby enhance bladder contractility. Although such an effect may be due solely to an α-adrenergic effect on the outlet, it may be that α-adrenergic blockade can, under certain circumstances, facilitate the detrusor reflex, through either a direct effect on parasympathetic ganglia or an indirect one.

Opioid Antagonists

Recent advances in neuropeptide physiology and pharmacology have provided new insights into LUT function and its potential pharmacological alteration. It has been hypothesized that endogenous opioids may exert a tonic inhibitory effect on the micturition reflex at various levels, and agents such as narcotic antagonists may, therefore, offer possibilities for stimulating reflex bladder activity [1].

Naloxone

In one study on 15 patients with SCI, no significant cystometric changes following intravenous naloxone were noted [246]. Interestingly, 11 of these patients showed decreased perineal electromyographic (EMG) activity but no associated change in dyssynergia pattern was seen. Although this issue is intriguing, it is of little practical use at present. Side effects of naloxone include precipitating withdrawal in patients addicted to opioids and sedation [247].

Decreasing Outlet Resistance at the Level of the Smooth Sphincter

α-Adrenergic Antagonists

Whether or not one believes that there is significant innervation of the bladder and proximal urethral smooth musculature by postganglionic fibers of the sympathetic nervous system, one must acknowledge the existence of α- and β-AR sites in these areas [1]. The smooth muscle of the bladder base and proximal urethral contains predominantly α-ARs. The bladder body contains both types, with the β-type being more common.

The implication that α-adrenergic blockade could be useful in certain patients who cannot empty the bladder was first made by Kleeman in 1970 [248]. Krane and Olsson were among the first to endorse the concept of a physiological internal sphincter that is partially controlled by sympathetic stimulation of contractile α-ARs in the smooth musculature of the bladder neck and proximal urethra [249]. Furthermore, they hypothesized that some obstructions that occur at this level during detrusor contraction result from an inadequate opening of the bladder neck or an inadequate decrease in resistance in the area of the proximal urethra. They also theorized and presented evidence that α-adrenergic blockade could be useful in promoting bladder emptying in such a patient, one with an adequate detrusor contraction but without anatomic obstruction or detrusor external sphincter dyssynergia (DESD). Many others have subsequently confirmed the utility of α-blockade in the treatment of what is now usually referred to as smooth sphincter or bladder neck dyssynergia or dysfunction. Successful results, usually defined as an increase in flow rate, a decrease in PVR, and an improvement in the upper urinary tract appearance, can often be correlated with an objective decrease in MUCP.

One would expect such success with α-blockade in treating emptying failure to be least evident in patients with DESD, as reported by Hachen [250]. Although most would agree that α-blockers exert their favorable effects on voiding dysfunction primarily by affecting the smooth muscle of the bladder neck and proximal urethra, some information suggests that they may decrease striated sphincter tone as well. Much of the confusion about whether α-blockers have a direct, as opposed to indirect, inhibitory effect on the striated sphincter relates to the interpretation of observations of their effect on urethral pressure and periurethral striated muscle EMG activity in the region of the urogenital diaphragm. It is impossible to tell from pressure tracings alone whether a decrease in resistance in one area of the urethra is secondary to a decrease in smooth or striated muscle activity.

α-Adrenergic blocking agents have also been used to treat both the bladder and outlet abnormalities in patients with the so-called autonomous bladders [251]. These include those with myelodysplasia, sacral or infrasacral SCI, and voiding dysfunction following radical pelvic surgery. Parasympathetic decentralization has been reported to lead to a marked increase in adrenergic innervation of the bladder, resulting in conversion of the usual β-(relaxant) bladder response to sympathetic stimulation to an α-(contractile) response [252]. Although the alterations in innervation have been disputed, the alterations in receptor function have not. Koyanagi [253] demonstrated urethral supersensitivity to α-adrenergic stimulation in a group of patients with autonomous neurogenic bladders, implying that a change had occurred in adrenergic receptor function in the urethra following parasympathetic decentralization. Parsons and Turton [254] observed the same phenomenon but ascribed the cause to adrenergic supersensitivity of the urethral smooth muscle caused by parasympathetic decentralization. Nordling and colleagues [255] described a similar occurrence in women who had undergone radical hysterectomy and ascribed this change to damage to the sympathetic innervation.

The most common adverse effects reported with this class of drugs are orthostatic hypotension, abnormal or retrograde ejaculation, dizziness, diarrhea, thirst, nasal congestion, and headache. Rarely, intraoperative floppy iris syndrome can occur and cause complications of cataract surgery. There are insufficient data to conclude whether there are additive hypotensive effects with concomitant PDE-5 inhibitor use for all α-antagonists. α-Blockers are metabolized primarily by the liver, predominantly via CYP3A4 [256].

Phenoxybenzamine

Phenoxybenzamine (POB) was the α-adrenolytic agent originally used for the treatment of voiding dysfunction; it has blocking properties at both α_1- and α_2-receptor sites. Nordling and colleagues [257] demonstrated that POB and clonidine, both of which pass the blood–brain barrier, decreased urethral pressure in the striated sphincteric area but had no effect on EMG activity. They concluded that the effect of clonidine and possibly POB was elicited mostly through centrally induced changes in striated urethral sphincter tonus, and that these agents also had an effect on the smooth muscle component of urethral pressure. POB is capable of increasing bladder compliance thereby increasing storage and decreasing urethral resistance thus facilitating emptying. The initial adult dosage of this agent is 10 mg daily, and the usually daily dose for voiding dysfunction is 10–20 mg. After the drug has been discontinued, the effects may persist for days because the drug irreversibly inactivates α-receptors, and the duration of effect depends on the rate of receptor synthesis [258]. Side effects include orthostatic hypotension, reflex tachycardia, nasal congestion, diarrhea, miosis, sedation, nausea, and vomiting.

McGuire and Savastano [259] reported that POB decreased filling cystometric pressure in the decentralized primate bladder. None of these drugs, however, affected the reflex rise in either urethral pressure or EMG activity that was seen during bladder filling, and none decreased the urethral pressure or EMG activity response to voluntary contraction of the pelvic floor striated musculature.

Prazosin

In the cat, Gajewski and colleagues [260] concluded that α-blockers do not influence the pudendal nerve-dependent urethral response through a peripheral action, but prazosin, at least, can significantly inhibit this response at a central level. In 10 healthy female volunteers, Thind and coworkers [261] reported on the effects of prazosin on static urethral sphincter function. They found that the function was diminished, predominantly in the midurethral area, and hypothesized that this response was due to a decrease in both smooth and striated sphincter muscle tone, the latter as a result of a reduced somatomotor output from the CNS. α-Adrenergic blockade can also decrease bladder contractility as Jensen [262] reported, with an increase in the “α-adrenergic effect” in the bladders characterized as “uninhibited.” Short- and long-term prazosin administration increased bladder capacity and decreased the amplitude of contractions. Prazosin is a potent selective α_1-antagonist [258], with a duration of action of 4–6 hours. Therapy is generally begun in daily divided doses of 2–3 mg and can be gradually increased to a maximum daily dose of 20 mg. Side effects are similar to those listed earlier for POB. Prazosin is contraindicated in patients taking PDE-5 inhibitors.

Terazosin and Doxazosin

Terazosin and doxazosin are two selective postsynaptic α_1-blocking drugs. They have a long plasma half-life enabling their activity to be maintained over 24 hours following a single dose [263]. These drugs are most often used for the treatment of benign prostatic hyperplasia (BPH) in men due to the high α_1-receptor content of the prostate stroma and capsule. Daily doses range from 1 to 10 mg and is generally given at bedtime. Terazosin is said to have the same affinity for α_1-receptors in genitourinary as in vascular tissue and a fourfold greater selectivity for α_1-receptors than doxazosin.

Swierzewski and colleagues [264] prospectively studied the effects of terazosin on 12 patients with SCI and decreased compliance. All patients were refractory to medical therapy and on CIC. Urodynamic studies were conducted before, during, and at the conclusion of 4 weeks of therapy with 5 mg of terazosin daily. The authors found statistically significant improvements in the bladder compliance, “safe bladder volume,” and bladder pressure in all patients, with the additional benefits of decreased episodes of both urinary incontinence and autonomic dysreflexia. They speculated that the improvement was due either to a direct effect on the α-receptors of the detrusor or to a central effect but not to any effects on outlet resistance. Terazosin is contraindicated in patients taking PDE-5 inhibitors.

Tamsulosin and Alfuzosin

Tamsulosin is an α_1-blocking agent that is selective for the α_{1a}- and α_{1d}-receptor subtypes over the α_{1b}-subtype [265]. It appears to have no significant drug-related adverse effects over placebo and has less effect on blood pressure than alfuzosin. The effects of tamsulosin on resting tone and contractile behavior of the urethra in 11 healthy females were studied using urethral pressure profilometry [266]. The drug significantly reduced the mean and MUP in the proximal, middle, and distal thirds of the urethra without any effect on systemic blood pressure. In a study on the functional bladder neck obstruction diagnosed by video urodynamics, 18 women were treated with tamsulosin 0.4 mg daily for at least 30 days [267]. Repeats of video urodynamics were performed with 56% of patients showing improvement in maximum flow, PVR, and symptoms. Tamsulosin 0.2 mg daily was studied in 97 women with chronic voiding symptoms and subnormal uroflow rates [268]. After 6 weeks of treatment, all patients experienced significant improvements in symptoms score, flow rate, and PVR, with 35.1% of the women achieving a >50% reduction in voiding symptom score and >30% increase in maximal flow rate. Only one patient in this study discontinued therapy due to intolerable dizziness. Tamsulosin was also studied in a RCT involving 364 women with OAB [269]. No difference was seen in primary or secondary outcome variables. Tamsulosin was well tolerated with 4.7% of women discontinuing treatment due to adverse events. Further, well designed, RCTs are needed to document tamsulosin’s effect on the LUT in women.

Recent molecular characterization of the α_1-receptor has led to the recognition, classification, and cloning of a number of α_1-receptor subtypes. In the human prostate, there appears to be some tissue specificity in that the majority of the stromal α_1-receptors are of the α_{1a}-subtype [270]. A drug selective to the α_{1a}-subtype would be expected to cause fewer undesired effects than the less selective drugs while maintaining clinical efficacy.

Alfuzosin is a new agent that is reported to be a selective and competitive antagonist of α_1-mediated contraction of the bladder base, proximal urethral smooth muscle, and prostate capsule (in men), with efficacy similar to that of prazosin [271]. It is said to be more specific for receptors in the genitourinary tract than in the vasculature, raising the possibility that voiding may be facilitated by doses that have minimal vasodilatory effects, thus minimizing postural hypotension. A sustained release form of the drug, which allows for once-daily dosing, is available. In a placebo-controlled study [272], it was shown to have no significant incidence of adverse effects above those of placebo. In addition, effects on blood pressure (orthostatic hypotension) were minimal, supporting its selectivity of the LUT over the vasculature.

Silodosin

Silodosin is a very selective α_{1a}-antagonist with minimal α_{1b} binding and therefore minimal cardiovascular side effects. The drug has encouraging phase III data for the treatment of LUTSs in men. There are no data available in women.

Agents with α-adrenergic blocking properties have been used in patients with various types of voiding dysfunction including functional outlet obstruction, urinary retention, decreased compliance, and neurogenic and idiopathic DO. Although there remains a paucity of data regarding the use of α-blockers in women, our experience suggests that a trial of such an agent is certainly worthwhile because its effect or noneffect should become obvious in a matter of days and the pharmacological side effects are reversible. However, our results with such therapy for non-BPH-related dysfunction have not been spectacular.

Decreasing Outlet Resistance at the Level of the Striated Sphincter

No class of pharmacological agents selectively relaxes the striated musculature of the pelvic floor. Three different types of drug, all generally characterized as antispasticity drugs, have been used to treat voiding dysfunction secondary to outlet obstruction at the level of the striated sphincter: benzodiazepines (diazepam), baclofen, and dantrolene. Diazepam and baclofen act predominantly within the CNS, whereas dantrolene acts directly on skeletal muscle. Although these drugs are capable of providing variable relief in specific circumstances, their efficacy is far from complete, and troublesome muscle weakness, adverse effects on gait, and other side effects limit their overall usefulness. Benzodiazepines and baclofen are thought to exert their effects on the LUT through interactions with inhibitory neurotransmitters in the CNS, γ-aminobutyric acid (GABA), and glycine [273]. The specific substrate for spinal cord inhibition consists of the synapses located on the terminals of the primary afferent fibers. GABA is the transmitter secreted by these synapses and activates specific receptors, resulting in a decrease in the amount of excitatory transmitter released by impulses from primary afferent fibers, consequently reducing the amplitude of the excitatory postsynaptic potentials.

Benzodiazepines

Benzodiazepines potentiate the inhibitory actions of GABA at pre- and postsynaptic sites in the brain and spinal cord [274]. When presynaptic inhibition is augmented, and it is thought that the release of excitatory transmitters from afferent fibers is reduced, thereby diminishing the stretch and flexor reflexes in patients with bladder spasticity. This is a postulated mechanism of action of the muscle relaxant properties of diazepam at least [275]. Side effects include nonspecific CNS depression, manifested as sedation, lethargy, drowsiness, slowing of thought processes, ataxia, and decreased ability to acquire or store information.

There are few available published papers that provide valuable data on the use of benzodiazepines for the treatment of functional obstruction at the level of the striated sphincter. We have not found the recommended oral dose of diazepam effective in controlling the classic type of DESD secondary to neurological disease. If the cause of incomplete emptying in a neurologically normal patient is obscure and the patient has what appears urodynamically to be inadequate relaxation of the pelvic floor striated musculature (e.g., occult neuropathic bladder, the Hinman syndrome), a trial of such an agent may be worthwhile. The rationale for its use is either relaxation of the pelvic floor striated musculature during bladder contraction or that such relaxation removes and inhibitory stimulus to reflex bladder activity. However, improvement under such circumstances may simply be due to the antianxiety effect of the drug or to the intensive explanation, encouragement, and modified biofeedback therapy that usually accompanies such treatment in these patients.

Baclofen

Baclofen depresses excitation of motor neurons in the spinal cord and was originally thought to function as a GABA agonist [275]. However, its electrophysiological and pharmacological profiles differ radically from those of GABA. Because both GABA and baclofen can produce some effects that are insensitive to blockade by classic GABA antagonists, two classes of GABA receptors have been proposed: the $GABA_A$ receptor (the classic receptor) and the $GABA_B$ receptor. Baclofen does not bind strongly or specifically to classic $GABA_A$ receptors but does to the $GABA_B$ receptors in the brain and spinal membranes. Accordingly, the primary sites of action of baclofen are the spinal cord and brain. Its effect in reducing spasticity is caused primarily by normalizing interneuron activity and decreasing motor neuron activity [159].

Drug delivery often frustrates adequate pharmacological treatment, and baclofen is a good example of this. GABA's hydrophilic properties prevent it from crossing the blood–brain barrier in sufficient amounts to make it therapeutically useful. Baclofen was developed as a more lipophilic analog of GABA; however, its passage through the barrier is likewise limited, and it has proved to be a generally insufficient when given orally to treat severe somatic spasticity and micturition disorders secondary to neurogenic dysfunction [276]. Hachen [250] found that a daily oral dose of 75 mg was ineffective in patients with DESD and traumatic paraplegia, whereas a daily intravenous dose of 20 mg was highly effective. Leyson and associates [235] reported that 73% of their patients with voiding dysfunction secondary to acute and chronic SCI had lower striated sphincter responses and decreased PVRs following baclofen treatment, but only with an average daily oral dose of 120 mg. Intrathecal infusion bypasses the blood–brain barrier and cerebrospinal fluid levels 10 times higher than those reached with oral administration are achieved with much lower doses [277]. Direct administration into the subarachnoid space by an implanted infusion pump has shown promising results, not only for skeletal spasticity but also for DESD and DO. Nanninga and colleagues [278] reported on such administration to seven patients with intractable bladder spasticity: all patients experienced a general decrease in spasticity and the amount of striated sphincter activity during bladder contraction. The action of baclofen on DO is not unexpected, given its spinal cord mechanism of action, and this inhibition of bladder contractility when the drug is administered intrathecally may, in fact, prove to be its most important benefit.

Potential side effects of baclofen include drowsiness, insomnia, rash, pruritus, dizziness, and weakness. Sudden withdrawal has been shown to provoke hallucinations, anxiety, and tachycardia; hallucinations due to reductions in dosage during treatment have also been reported [214]. Development of tolerance to intrathecal baclofen with a consequent requirement for increasing doses may prove to be a problem with long-term chronic usage. Further studies on the long-term efficacy of intrathecal baclofen specifically on the LUT in patients with neurogenic bladder are anticipated.

Dantrolene

Dantrolene exerts its effect by direct peripheral action on skeletal muscle [279]. It is thought to inhibit the excitation-induced release of calcium ions from the sarcoplasmic reticulum of striated muscle fibers, thereby inhibiting excitation-contraction coupling and diminishing the mechanical force of contraction. The drug improves voiding function in some patients with classic DESD and was initially reported to be very successful in doing so [280]. In adults, the recommended starting dose is 25 mg daily, gradually increasing by increment of 25 mg every 4–7 days to a maximum oral dose of 400 mg given in four divided doses. Hackler and colleagues [281] reported an improvement in voiding function in approximately half of their patients treated with dantrolene but found that such improvement required oral doses of 600 mg daily. Although no inhibitory effect on bladder smooth muscle seems to occur [282], the generalized weakness that dantrolene can induced is often sufficiently significant to compromise its therapeutic effects.

Potential side effects other than severe muscle weakness include euphoria, dizziness, diarrhea, and hepatotoxicity. Fatal hepatitis has been reported in 0.1%–0.2% of patients treated with the drug for 60 days or longer and symptomatic hepatitis may occur in 0.5% of patients treated for more than 60 days; chemical abnormalities of liver function are noted in up to 1%. The risk of hepatic injury is twofold greater in women [107].

BTX

BTX, a potent inhibitor of ACh release at the neuromuscular junction, has been injected directly into the striated sphincter to cause relaxation in the treatment of DESD [283]. This application has led to the use of BTX in treating neurogenic and nonneurogenic causes of urethral sphincter hypertonicity that may lead to retention. Injections of 100 units of BTX-A weekly for 3 weeks can achieve duration of effect averaging 6–9 months. Fowler and colleagues [194] used BTX injection in six women with difficulty of voiding or urinary retention secondary to abnormal myotonus-like EMG activity in the striated urethral sphincter. Although voiding did not improve in any patient (attributed to the type of repetitive discharge activity present), three patients developed transient SUI, indicating that the sphincter muscle had, indeed, been weakened. Phelan and colleagues [284] performed a prospective study to assess the efficacy of injecting 80–100 units of BTX-A into the external sphincter of 13 women and 8 men with voiding dysfunction due to various causes, including DESD, pelvic floor spasticity, and bladder hypocontractility. All patients except one were able to void spontaneously, and all but two were able to discontinue catheterization. Similarly, Kuo injected 50 or 100 units of BTX-A into the urethra of 103 patients (55 women) with chronic urinary retention or severe difficulty urinating [202]. The reasons for the LUT voiding dysfunction were quite heterogeneous: DESD, dysfunctional voiding, nonrelaxing urethral sphincter, cauda equina lesion, peripheral neuropathy, and idiopathic detrusor underactivity. Subjectively, 39% had "excellent" results and 46% had "significant" improvement. There was a significant decrease in maximum voiding pressure, MUCP and PVR. In a small, double-blind RCT, the efficacy of BTX-A was compared with lidocaine [285]. This study was performed in 13 patients with DESD secondary to SCI. The injections were performed transperineally. BTX-A was superior to lidocaine, resulting in decreased PVR and MUP. Those treated with BTX-A also had an increase in patient satisfaction. Side effects of BTX were listed in pp. 429–431.

Clonidine

Clonidine is the prototypical α_2-adrenergic receptor agonist. It is considered to be a centrally acting agent with a variety of associated systemic effects including antihypertensive, antinociceptive, and antispasmodic effects. Potential effects on relaxation of the external urethral sphincter (EUS) have been reported previously [257]. Herman and Wainberg [286] administered oral clonidine (400 mcg) in three divided doses over a 16 hour period under monitored inpatient conditions to five patients with SCI with neurogenic DO and quantified effects on the EUS via needle electrodes. They found that clonidine had a profound suppressive effect on volume-induced EMG activity in the EUS in four of five patients. The one patient in whom there were only minimal effects on the EUS had received an intrathecal dose of morphine 2 days before, which the authors feel may have confounded the effects of clonidine in this patient. The authors speculate that the somewhat selective effect of clonidine on the EUS is attributable to postsynaptic suppression of excitatory spinal interneurons (unmasked by the spinal lesion) via the α_2-agonist activity of clonidine. Adverse effects included significant reductions in blood pressure and sedative effects. Further clinical studies on the effects of clonidine on the LUT and striated sphincter (as well as its clinical utility) may be limited owing to its significant effects on blood pressure.

CIRCUMVENTING THE PROBLEM

Antidiuretic Hormone-Like Agents

Endogenous production of antidiuretic hormone (ADH) serves two purposes: stimulation of water reabsorption in the renal medulla and contraction of vascular smooth muscle. A genetic or acquired defect in ADH synthesis or secretion results in central diabetes insipidus, while a defect in the ADH receptor results in nephrogenic diabetes insipidus. A relative lack in ADH is believed to be important in polyuria, specifically nocturnal polyuria [287].

Desmopressin

The synthetic ADH analog, desmopressin (DDAVP), has been used for the symptomatic relief of refractory nocturnal enuresis in children and adults [288]. More recently, it has been explored for the treatment of OAB and incontinence. The drug can be administered by oral, parenteral, or intranasal spray and effectively suppresses urine production for 7–10 hours.

Several small controlled studies on patients with multiple sclerosis and nocturia have consistently reported efficacy of DDAVP at the risk of asymptomatic or minimally symptomatic hyponatremia [289]. Further studies in nonneurological patients have confirmed the efficacy and determined effective dose regimens for the treatment of nocturia [290]. In a phase IIb study on the use of oral DDAVP in the treatment of OAB symptoms, a decrease in frequency and urgency episodes was observed. Patients also reported an improvement in HRQL with only mild side effects including headache. No hyponatremia was reported [291]. Further studies on DDAVP for the treatment of OAB and incontinence are needed.

Given the safety concerns over hyponatremia, it is recommended that the drug not be given in patients older than 79 years of age or to those with 24 hour urine volumes >28 mL/kg. It is also recommended that serum sodium levels be checked at baseline and at 3 and 7 days after starting treatment or changing dose [292]. General precautions including limiting fluid intake from 1 hour before the dose until 8 hours after, periodic blood pressure measurements, and weight measurements to monitor for fluid overload should be instituted. The original intranasal spray has been withdrawn from the market in several countries due to side effects and unpredictable absorption. Side effects include headache, hyponatremia, water intoxication, and rhinitis. DDAVP is contraindicated in patients with baseline hyponatremia and moderate to severe renal impairment [293].

Loop Diuretics

Bumetanide

A similar circumventive approach is to give a rapidly acting loop diuretic 4–6 hours before bedtime. This, of course assumes that the nocturia is not due to obstructive uropathy. A double-blind, crossover RCT of this approach using bumetanide 1 mg was performed in a group of 14 general practice patients [294]. Nocturia episodes per week averaged 17.5; with placebo, this decreased to 12 and with drug to 8. Bumetanide was preferred to placebo by 11 of 14 patients. Side effects include hyperuricemia, hypochloremia, hypokalemia, hyponatremia, hyperglycemia, and serum creatinine elevation [295].

47 Peripheral Neuromodulation

John Heesakkers and Jetske van Breda

INTRODUCTION

Neuromodulation of the lower urinary tract is extensively applied in patients with overactive bladder (OAB) complaints. The best known and best documented technique is sacral nerve stimulation. Posterior or percutaneous tibial nerve stimulation (PTNS) is the second most extensively documented way of nerve stimulation. The exploration of the best technique of electrical stimulation of the lower urinary, including sex organs, is guided by three principles:

1. Stimulation should be done via the least invasive way. For this reason transcutaneous stimulation with surface electrodes or stimulation probes would suit best.
2. Stimulation should be in an area that is acceptable and not embarrassing for patients.
   This makes sacral dermatomes or legs appropriate areas for stimulation.
3. Stimulation should be practical to apply.
   Continuous stimulation is therefore less ideal and discontinuous stimulation is easier than continuous stimulation

METHODS OF PERIPHERAL NEUROMODULATION

The nerves that innervate the lower urinary tract originate from the lumbar, sacral, and coccygeal segmental nerves from L2 to S4 (Figure 47.1). Afferent and efferent fibers from these segmental sacral roots merge in the periphery outside the spinal cord. After merging, the nerve fibers continue as combined nerves that have lost their segmental innervation pattern. The sciatic nerve is composed of fibers from L4 to S3. The posterior tibial nerve is a part of the sciatic nerve. Peripheral neuromodulation of the lower urinary tract has been attempted via stimulation of those nerves that are related or involved in pelvic organ innervation. These are the pudendal nerve (PN), the dorsal genital nerve (DGN), and the posterior tibial nerve. Peripheral neuromodulation can also be done via the overlying skin or by stimulating the dermatomes that are innervated by the same nerve as the ones that innervate the lower urinary tract.

This chapter describes the clinical practice and developments of the peripheral neuromodulation systems, in particular PTNS, PN stimulation, and DGN stimulation.

PTNS

History

It is an ancient Chinese custom to perform acupuncture of the lower leg. With this technique, developed in China over 5000 years ago, the "energetic harmony" of the urogenital tract might be restored by way of stimulation of specific points. Wilhelmus ten Rhyne (1647–1700) was a Dutch physician who was employed by the Dutch East India Company in 1673 where he encountered eastern traditional medicine. In 1683 he published a book entitled *Dissertatio de Arthritide: Mantissa Schematica: De Acupunctura: Et Orationes Tres* [1]. He wrote about the art of needling for treating diseases including those of the lower urinary tract. He called this technique "acupunctura," and it was the first Western detailed study on that matter.

One of the most commonly used acupuncture points used for gynecological, fertility, digestive, urinary, sexual, and emotional disorders is the *SanYinJiao point*, or spleen 6. It can be translated as "three yin intersection" because it is the meeting point of the three yin channels of the leg: spleen, liver, and kidney. SanYinJiao, SP-6 or spleen 6 is located on the medial side of the lower leg, about 6–8 cm cephalad to the prominence of the medial malleolus. It lies close to the medial crest of the tibia. The location of the SP-6 acupuncture point and the organs affected by this kind of acupuncture have remarkable similarities with PTNS. When electrical current is applied to the acupuncture needle, the technique is called electrical acupuncture. Especially when electroacupuncture is performed with similar stimulation parameters (2–15 Hz, 10–20 mA), it is likely that nerve stimulation is responsible for the clinical effect. Similar effects as with tibial nerve stimulation therefore might be expected on the pelvic organs perhaps as well as on the spleen and on the liver.

The fundamental feature of neuromodulation as compared to acupuncture is that nerves are stimulated and not energy pathways or other routes that do not have any anatomical substrate. Nerve stimulation ideally has an efferent motor effect and an afferent sensory effect. Stimulation of posterior tibial nerve results in great toe flexion or fanning of the toes. The sensory effect is a radiation tickling sensation of the foot sole. McGuire was the first to explore tibial nerve stimulation in 1983 [2]. He performed transcutaneous PTNS in 15 patients with detrusor overactivity (DO) because of a neurological disease.

Inspired by this previous work by McGuire, Marshall Stoller started research on PTNS as neuromodulative treatment in lower urinary tract dysfunction. After initial testing in pig-tailed monkeys, PTNS was later investigated in humans with promising results [3]. This new initiative was the start of the worldwide development and exploration of PTNS.

Historic Overview

5000 BC	Acupuncture of the lower leg in China.
1683 AD	Wilhelmus ten Rhyne writes *Dissertatio de Arthritide: Mantissa Schematica: De Acupunctura: Et Orationes Tres*.
1983	McGuire performs transcutaneous PTNS.
1987	PTNS by Stoller.
1999	Clinical introduction of PTNS.
2006	First publication on tibial nerve implant by van der Pal.
2009	First randomized controlled trial by Peters.

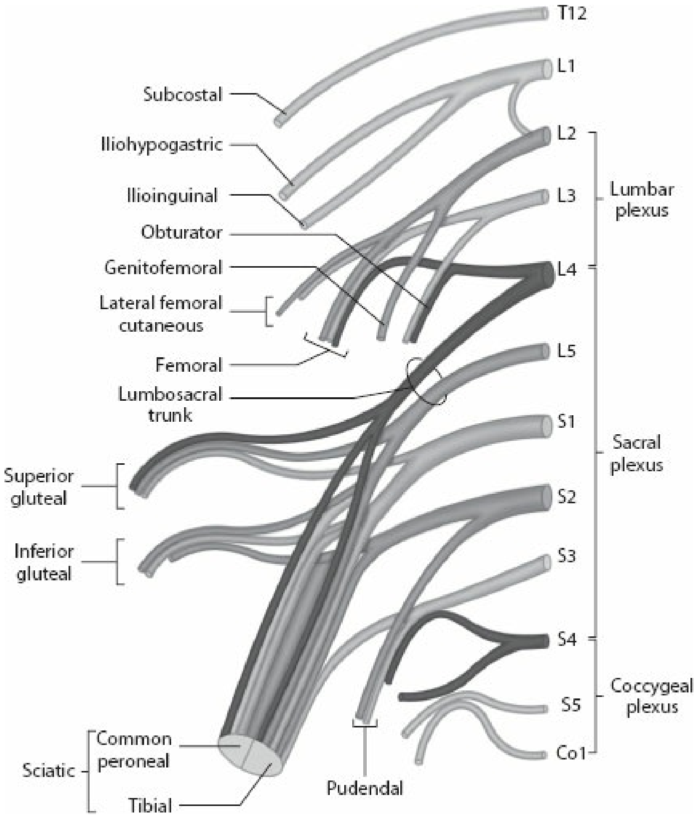

Figure 47.1 Organization of the lower lumbar, sacral, and coccygeal nerve plexus, the merger of the various roots and the most important nerves that branch from the merged nerve plexus. The tibial nerve has its offspring in the sacral roots of mainly S2 and S3.

Technique

PTNS is performed in patients placed in the supine position with the medial malleolus pointing upward. A 34-gauge stainless steel needle is inserted approximately 3–4 cm, about three fingerbreadths cephalad to the medial malleolus, between the posterior margin of the tibia and soleus muscle. The insertion depth is about 2 cm. A stick-on electrode is placed on the same leg near the arch of the foot. The needle and electrode are connected to a low voltage (9 V) stimulator (Urgent PC®, Uroplasty, Inc., Minnetonka, MN) with an adjustable pulse intensity of 0–10 mA, a fixed pulse width of 200 microseconds and a frequency of 20 Hz (Figure 47.2). During the initial test stimulation the amplitude is slowly increased until the large toe starts, to curl or toes start to fan. If the large toe does not curl or pain occurs near the insertion site, the stimulation device is switched off and the stimulation again is switched on for the final proper stimulation phase. If the large toe curls or toes start to fan, stimulation is applied at an intensity well tolerated by the patient. If necessary, the amplitude can be increased during the session. In general, patients undergo 12 outpatient treatment sessions, each lasting 30 minutes 1–3 times per week. If a good response occurs, the patient is offered chronic treatment [4].

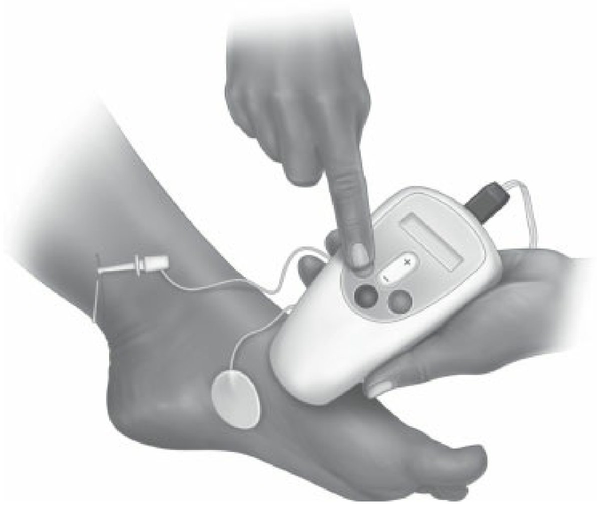

Figure 47.2 Technique of posterior or percutaneous tibial nerve stimulation. (From Heesakkers JPFA, Vierhout ME, *Het urine-incontinentie formularium 2E*, BSvL, Ak Houten, the Netherlands, 2012. With permission.)

Working Mechanism

At the moment, the exact working mechanism of neuromodulation, including PTNS, is still not completely understood. However, it is postulated that symptoms of OAB including incontinence may represent an alteration of the pelvic neuromuscular environment via changes in the inhibitory and excitatory signals of the voiding reflex. It is thought that electrical stimulation of the sacral nerve roots modulates the afferent neural reflex pathways between the spinal cord or pons and pelvic organs. As the ascending sensory pathway inputs and guarding reflex pathway are modulated, storage may be facilitated.

Blok et al. looked at the effects of acute and chronic sacral neurostimulation on PET images of the brain [5]. In the acute phase, brain areas are involved that have to do with sensorimotor learning. These are the areas located in the right postcentral gyrus, the left parietal cortex, the medial prefrontal cortex, and the right insula. Furthermore, there was activation in the ventromedial orbitofrontal cortex and decreased activation in the left medial cerebellum.

However, chronic sacral neurostimulation decreased activity in the cerebellum, midbrain, and adjacent midline thalamus and limbic cortical areas, previously implicated in the control of micturition and urinary storage. They postulated that neuromodulation modulates predominantly areas involved in sensorimotor learning, which might become less active during the course of chronic SN.

In an analogy to sacral neuromodulation, central effects have been studied in PTNS. Finazzi Agro et al. studied the effect of PTNS and sham stimulation on short-latency somatosensory evoked potentials

(SL-SEPs) and long-latency somatosensory evoked potentials (LL-SEPs) [6]. Somatosensory evoked potentials (SEPs) reflect information processing in the brain after stimulation of peripheral somatosensory system. In particular, LL-SEPs seem to provide information on the function of somatosensory associative cortical structures. LL-SEP changes imply that durable stimulation (1 day after treatment) changes in SEP occur. They showed that the amplitude of LL-SEP changes of P80 and P100 waves in the active PTNS group was significantly higher as compared to the placebo group.

The recorded P80 and P100 amplitude increase might reflect long-term modifications in synaptic efficiency through the somatosensory pathway induced by repetitive peripheral nerve stimulation. Long-term potentiation (LTP) and depression (LTD) of excitatory synaptic transmission can contribute to experience-dependent modifications of brain function, including learning and memory. Thus, a plastic reorganization of cortical network triggered by peripheral neuromodulation can be hypothesized as a mechanism of action of PTNS. They concluded that PTNS effects are mediated by suprasacral centers of stimulus elaboration involving cortical associative areas. This is in line with the theories about the working mechanism of sacral nerve stimulation. Such a mechanism of action may, in part, explain the clinical effects of this therapy, which seem to be sustained for an extended period of time (weeks to months) following the conclusion of stimulation.

If one considers applying PTNS for improvement of clinical conditions one has to accept that

- It is possible to positively influence the innervation system of the lower urinary tract by stimulation of the tibial nerve at the ankle
- There is no direct sensation in the bladder area nor motor action of muscles in or adjacent to the pelvic floor during tibial nerve stimulation
- Discontinuous stimulation during a limited period of time once to thrice a week is sufficient to have a beneficial affect

Clinical Results

Since the introduction of PTNS in 1999, several studies have been performed evaluating its effectiveness especially in patients with OAB dry and OAB wet and nonobstructive urinary retention.

Almost all studies on OAB used micturition diaries and general and/or disease-specific quality of life questionnaires to measure the effects of PTNS [7,8]. Subjective success was found in 59%–64% of patients. Objective success, defined most of the time as more than 50% decrease in incontinence episodes and/or micturition frequency, was found in 47%–56% of patients [8,9].

Urodynamic studies especially measured by cystometry may provide more objective data on the efficacy of PTNS. When acute PTNS is performed as soon as DO is observed during cystometry, the suppressive effects in neurological patients are contradictory [10,11].

In these studies, frequency/volume chart data and quality of life scores improved significantly. However, of the participants with pre- and post-treatment urodynamic data, only a few showed complete abolishment of DO [12]. Nevertheless, increments in cystometric bladder capacity and in volume at occurrence of DO were significant. Subjects without DO at baseline appeared 1.7 times more prone to respond to PTNS. The more the bladder overactivity was pronounced, the less these patients were found to respond to PTNS.

Once a positive treatment outcome has been obtained with PTNS, a maintenance program is needed to avoid recurrence of symptoms. One study evaluated the necessity of maintenance therapy by means of a 6-week pause of therapy in successfully treated PTNS patients, leading to over 50% worsening of the main symptoms in almost all patients. Restarting PTNS afterward improved complaints to the level present before the break in treatment [13].

One of the most important studies on PTNS was performed by Peters et al. [14]. The so-called Study of Urgent PC versus Sham Effectiveness in Treatment of Overactive Bladder Symptoms (SUmiT) was a multicenter, double-blind, randomized, controlled trial comparing the efficacy of PTNS to sham through 12 weeks of therapy. The breakthrough was that a validated sham arm was developed and used as a comparator. This was the first time that the net effect apart from the placebo effect could be measured. In two groups of 110 patients, the improvement in global response assessment (GRA), voiding diary parameters, and OAB and quality of life questionnaires were evaluated. The GRA is a self-reported 7-point scale that tells whether an individual perceives a change due to the treatment. Individuals who noted a moderate or marked improvement were regarded as successfully treated patients. Voiding diary parameters after 12 weeks of therapy showed PTNS subjects had statistically significant improvements in frequency, nighttime voids, voids with moderate to severe urgency, and urinary urge incontinence episodes compared to sham. The GRA in the PTNS subjects showed that 55% reported moderately or markedly improved responses as compared to 21% in the sham group.

Another sham-controlled study was performed by Finazzi et al. with similar results [15].

PTNS implies that patients will have to have repeat treatments. The tapering studies show that once every 2 or 3 weeks is sufficient in those patients that benefit from PTNS. Another major question is what the long-term success of PTNS is. Peters et al. followed 50 participants from the SUmiT trial who met the primary effectiveness endpoint after 12-weekly PTNS [16]. These patients were prescribed a fixed-schedule 14-week tapering protocol followed by a personal treatment plan aimed at sustaining OAB symptom improvement. Of this group, 29 patients completed the 36-month protocol and received a median of 1.1 treatments per month. At 3 years 77% maintained moderate or marked improvement in OAB symptoms. Compared to baseline, median voids per day decreased from 12.0 to 8.7, and urge incontinence episodes per day decreased from 3.3 to 0.3. All quality of life parameters remained markedly improved from baseline through 3 years. Minor side effects were described. They were related to needle insertion and consisted of bruising (0.9%), discomfort (1.8%), and bleeding (2.7%).

- PTNS improves OAB symptoms based on voiding diary parameters in 47%–56%.
- Subjective improvement is obtained in about 60% of patients.
- PTNS increases cystometric capacity and delays the onset of, but does not abolish, DO.
- Maintenance therapy is necessary to sustain the effect of therapy.
- PTNS improved bladder symptoms measured with GRA in 55% as compared to 21% in a sham treated group.
- After 3 years, 77% of responding patients to initial therapy experienced moderate to marked improvement on OAB symptoms.

PROGNOSTIC FACTORS FOR PTNS

Little data are available about prognostic factors for success or failure of PTNS. Studies on urodynamic changes by PTNS suggest that in the setting of OAB, without DO, patients are more prone to a successful treatment outcome [12]. Clinical parameters for predicting sacral nerve stimulation (SNS) outcome were also tested in 132 patients treated with PTNS, but showed no significance [17]. Also, a history of sexual and/or physical abuse did not alter PTNS treatment outcome. However, a low total score at baseline in the SF-36 general quality of life questionnaire proved to be predictive for not obtaining objective nor subjective success. Patients with a low SF-36 mental component summary were especially prone to fail. These patients also scored worse on disease-specific quality of life questionnaires, although they had no difference in disease severity compared to patients with good mental health.

- Subjects with mental/cognitive problems don’t seem to be ideal candidates for PTNS

URGENT-SQ: THE PTNS IMPLANT

Rather quickly after the modern clinical development of PTNS, it was recognized that the repeated return to the clinic, once weekly or once bi- or triweekly, would finally lead to a logistic problem with patients returning to the clinic approximately 1–2 times per month. If all successfully treated patients would return every week, this would lead to a jammed outpatient clinic. More importantly, the travel burden for patients would be high and PTNS treatment on demand would not be possible. Therefore, an implant was developed that was placed at the tibial nerve at the ankle and that could be operated via radiofrequency activation with an external stimulator: the Urgent-SQ (Figures 47.3 and 47.4).

The pioneering work was done by van der Pal et al. [18]. They looked at eight patients with refractory OAB who were treated with the Urgent-SQ. After implanting the device, the patients could operate the implant by means of an external stimulator. Patients were evaluated at 3, 6, and 12 months of follow-up. The primary objective was ≥50% reduction in the number of incontinence episodes and/or voids on bladder diary. At 3, 6, and 12 months, respectively, 5, 6, and 4 patients met the primary objective. At 3- and 6-month follow-up, voiding and quality of life parameters had significantly improved. Urinary tract infection, temporary walking difficulties, and spontaneous radiating sensations were reported as adverse events, and there was no local infection, erosion, or dislocation.

Janssen et al. reported about the long-term efficacy and safety of these patients in an open-label study [19]. The seven patients who still had the implant were contacted after nine years and evaluated with an interview, physical examination, ankle x-ray, voiding diaries, and completed questionnaires about adverse events, performance, efficacy, safety, and quality of life with the validated I-QoL. Results showed that six of the seven patients still had sensory and locomotor responses on stimulation at 9-year follow-up. Four patients who had a successful treatment response at one year still used the device. The implants were intact with no migration and/or displacement. Two patients experienced minor discomfort. The conclusion was that after 9 years, the Urgent-SQ implant was a safe therapy for OAB.

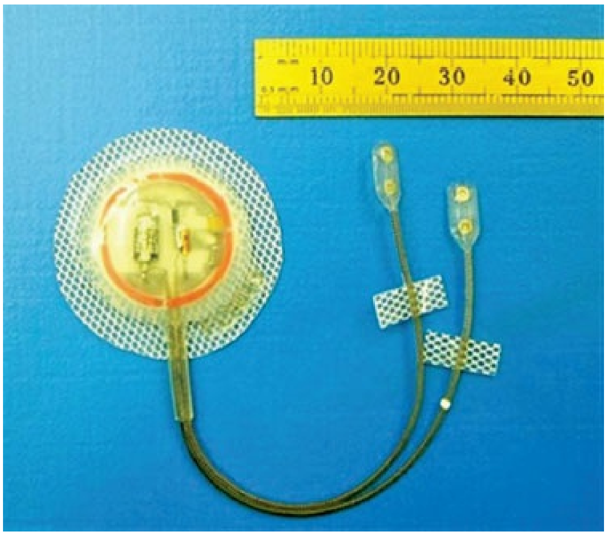

Figure 47.3 The Urgent-SQ implant consisting of an internal electromagnetic pulse receiver; the body, with two leads; and monopolar platinum electrodes.

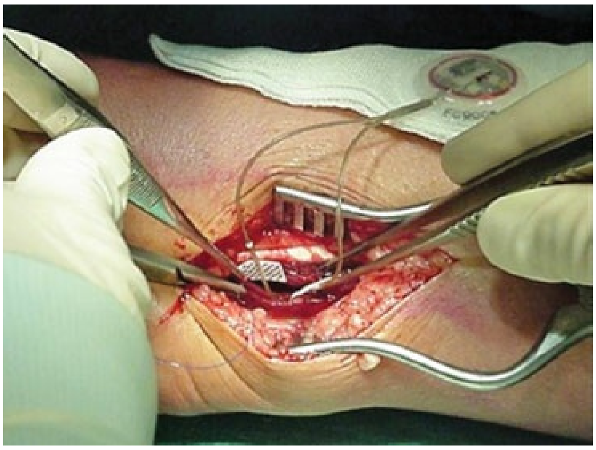

Figure 47.4 Site of implantation during surgery. The two electrodes are placed on opposite sides of the tibial nerve just proximal to the medial malleolus.

- A pilot study reveals that the Urgent-SQ implant appears to be a safe and effective treatment for OAB.

COSTS

Several manuscripts have been published about the cost-effectiveness of the various treatments for OAB, in particular for PTNS and SNS. Various articles show different costs since the medical care systems differ between countries. Leong published that the cost of SNS as a treatment for OAB syndrome in the Netherlands is $15.743 over a 2-year time period [20]. D'Ausilio calculated the 10-year cost for SNS in Italy at €33.897, whereas Staskin compared the costs of PTNS to SNS for OAB syndrome in the United States [21,22]. PTNS was the least costly ($7.565 for a 3-year treatment) compared to SNS ($24.681 for the same treatment period). Chen et al. calculated that 1 year of treatment with PTNS costs $4.375 per patient [23]. Martinson also concluded that PTNS had substantially lower costs compared to SNS in the United States [24]. Although there is variation between countries, it appears that PTNS is less costly as compared to SNS.

FUTURE PERSPECTIVES OF PTNS

PTNS is a minimally invasive, easily accessible neuromodulation technique and has proven its benefit in OAB and nonobstructive urinary retention. Regretfully, in chronic pelvic pain the effects seem to be only modest. At this moment, there is “circumstantial” evidence existing for its efficacy, based on animal studies, and clinical studies including urodynamic parameters. In case PTNS becomes a more established treatment modality, no doubt other indications will be explored. Subjects for further investigation of areas that already have some clinical efficacy data are children, neurological patients, and patients with fecal incontinence.

Almost all research done on PTNS used the same stimulation protocol: PTNS was performed in 10–12 weekly sessions, each lasting for 30 minutes. Stimulation parameters were preset and rather fixed and every time only one needle was inserted. It may well be anticipated that changes in treatment scheme and/or stimulation parameters could lead to a different, possibly even better outcome. The same goes for bilateral instead of unilateral therapy. It is evident that an accelerated stimulation scheme has the advantage of achieving clinical results faster [25]. Regarding stimulation parameters, it is rather widely agreed that pulse intensity in neuromodulation should be set at a well-tolerated level. As it is suggested that frequency is optimal at more unpleasantly low levels (5–6 Hz), studies on PTNS with pulse frequencies below 20 Hz may produce better results [26]. The same goes for changes in pulse duration. Currently, in PTNS, the standard setting is 0.2 milliseconds.

The recent revitalization of the Urgent-SQ creates other possibilities. Efforts should be undertaken to refine the preimplant testing phase in order to decrease the amount of unnecessarily treated patients. Hopefully, this will eventually lead to the ideal implant: an effective and safe, easily controllable device that is operated by patients themselves in flexible, individualized treatment schemes.

Apart from the clinically available and accepted PTNS and SNS treatments, two promising peripheral neuromodulation possibilities nowadays are used in experimental settings: PN stimulation and DGN stimulation.

PUDENDAL NERVE STIMULATION

The PN originates from the S2, S3, and S4 sacral nerve roots. It is a somatic nerve and innervates the external genitalia as well as both the external urethral sphincter and the external anal sphincter. The main trunk passes over the ischial spine and enters Alcock’s canal. Selection of the PN, as a site of stimulation, potentially provides afferent stimulation of S2, S3, and S4. The PN has three major branches, the inferior rectal nerve, the DGN, and the perineal nerve, with a high variation in branching patterns. Afferent PN stimulation has been demonstrated to inhibit the micturition reflex, to abolish uninhibited detrusor contractions, and to increase bladder capacity in animals and humans [26,27]. The potential advantage of PN stimulation compared to SNS is that PN stimulation recruits more afferent fibers. Since the presumed main working mechanism of all types of neuromodulation is in an afferent direction, the recruitment of as many afferent fibers as possible is optimal. Different approaches for electrical stimulation of the PN were described by Martens as is depicted in Figure 47.5 [28].

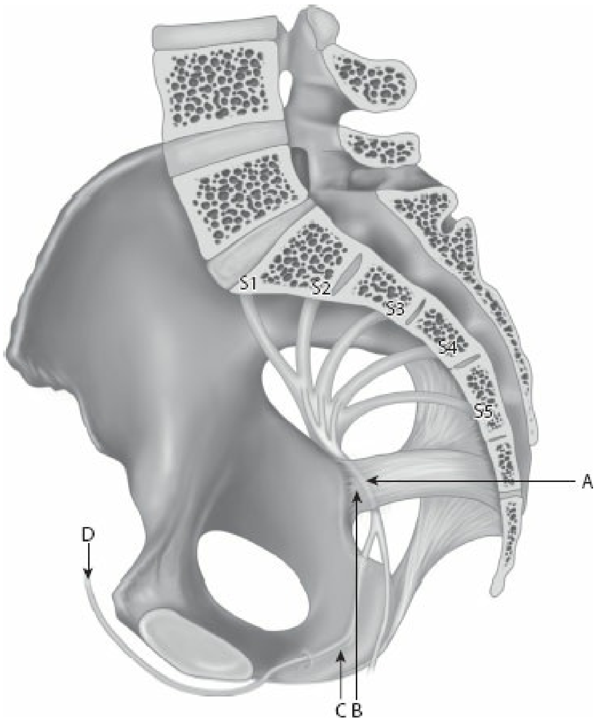

Figure 47.5 Approaches for electrical stimulation of the pudendal nerve (PN) and dorsal nerve of the penis or clitoris. The PN originates primarily from the second, third, and fourth sacral nerve roots (S2, S3, S4), and it sometimes gains contributions from the adjacent roots of S1 and S5. The PN can be accessed for stimulation at the ischial spine by a posterior (A) or perineum approach (B) for insertion of an electrode. With a perineum approach, the PN can also be reached at Alcock's canal (C). The dorsal genital nerve can be stimulated using surface electrodes or percutaneously implanted electrodes (D). (By courtesy of Frank Martens.)

The posterior approach using the ischial spine as a landmark can be accessed by inserting a wire electrode perpendicular at the intersection of a horizontal line from the greater trochanter with a vertical line from the ischial tuberosity tip. When one wants to approach the PN from the perineum, the electrode is inserted perpendicularly to the perineum between the ischial tuberosity and anus.

The use of chronic PN stimulation in refractory neurogenic urgency incontinence with a minimal invasive procedure was first reported by Spinelli in 2005 [29]. Fifteen patients underwent chronic PN stimulation, six with a perineal approach and nine with a posterior approach. Eight patients became continent, two improved by more than 88% and two reduced the number of incontinence episodes by 50%. In 12 patients with a response of >50% improvement in urge incontinence episodes, an implantable pulse generator (IPG) was implanted. At an average follow-up of 6 months, these patients with the implanted IPG perceived the same clinical efficacy as achieved during the screening phase. In the same year, a prospective randomized single-blind, cross-over trial of SNS versus PN stimulation was reported by Peters, including patients with urgency–frequency, urgency incontinence, and nonobstructive urinary retention [30]. Thirty subjects were implanted with a tined lead at S3 and a second electrode was implanted at the PN by the perineum approach. In a blinded, randomized fashion, each lead was tested for 7 days. An overall 50% improvement was considered as a positive response. Twenty-four patients responded to nerve stimulation. Of these, PN stimulation gave overall improvement in symptoms of 63%, whereas those with SNS reported an overall improvement of 46%. Of patients whose symptoms improved more than 50%, 79% desired to have PN stimulation compared to 21% for SNS. On the GRA scale, PN stimulation was superior to SNS for pelvic pain, urgency, frequency, and bowel function. No difference in voiding diary parameters was observed.

Continuous or conditional stimulation can be applied. Continuous stimulation produces stimuli constantly. With conditional stimulation, stimulation takes place when a certain condition such as an involuntary detrusor contraction (IDC) occurs. Conditional stimulation is considered as effective as continuous stimulation to increase bladder capacity, but it reduces stimulation time. This can lengthen the life span of an implanted battery and might prevent habituation to stimulation. Unfortunately, there is not yet a reliable autonomous warning signal for IDC that can be used as a trigger for the stimulation action. So far, only patient-controlled stimulation can be applied. The clinical benefit of patient-controlled stimulation has to be studied in future chronic clinical studies [28].

The literature on PN stimulation for OAB is encouraging but limited and indicates that PNS might be a reasonable option for OAB in the future when more successful long-term clinical results become available.

- PN stimulation still is experimental but has conceptual advantages over other types of neuromodulation.
- Few clinical studies exist that show at least a comparable clinical result as compared to sacral nerve stimulation.
- Broad clinical application and long-term data are awaited for PNS.

DORSAL GENITAL NERVE STIMULATION

The DGN, being either the dorsal penile nerve or the dorsal clitoral nerve, is a branch of the PN. After exiting the Alcock's canal anteriorly, the DGN continues cranially where it contacts the inferior ramus of the pubis and subsequently courses to the inferior border and anterior surface of the body of the pubis. In the male, the nerve courses proximal to the insertion of the cavernous body and continues between the cavernous body and the anterior surface of the pubis to the dorsum of the penis. The nerve divides and runs bilaterally on the dorsal side to the penis between the tunica albuginea and Buck's fascia to terminate in the penile gland. In the female, the nerve travels from the anterior surface of the body of the pubis then pierces the perineal membrane lateral to the external urethral meatus. It traverses along the bulbospongiosus muscle before traversing posteriorly to the crura. The nerve hooks over the crura to lie on the anterolateral surface of the body of the clitoris, before dividing into two cords and terminating short of the tip of the clitoral gland [28,31]. The DGN is running more superficial and therefore perhaps more suited for less invasive stimulation techniques. The mechanism of action of DGNS is thought to be by afferent stimulation of the PN. DGN stimulation is not yet used in daily clinical practice. All publications so far are about experiments in research settings.

Goldman performed DGN stimulation in 21 patients with nonneurogenic OAB using a percutaneously placed electrode [32]. Improvement was defined as a >50% reduction in each of the measured incontinence parameters: 24 hour pad test weight, incontinence episodes per day, pads per day, and the amount of severe urgency episodes. Of the 21 subjects, 19 completed the week of stimulation. In two subjects, the electrode failed, one broke and one dislodged. Of the 19 who completed the home stimulation week, 15 (79%) subjects reported a reduction in incontinence episodes and 9 (47%) experienced a >50% reduction in the number of incontinence episodes. Of those 9, the mean reduction of incontinence episodes a day was 89%. Of the 17 (47%), 8 used less than 50% of their pads per day as compared to pretreatment, whereas 13 (76%) of the 17 subjects who performed a 24 hour pad test had a >50% reduction in pad weight. Eight subjects (47%) were complete dry. With an average reduction of 82%, 13 (68%) had >50% reduction in severe urgency episodes. With regard to side effects, seven patients experienced side effects, ranging from skin irritation to pain and bruising around the electrode exit site. All were mild and recovered spontaneously within 11 days of the implant procedure. This study was the first to demonstrate the feasibility of DGN stimulation via a percutaneous electrode for treatment of urge incontinence in the nonneurogenic population. The results for DGN stimulation in this study are encouraging and seem to be comparable to results of other methods of neuromodulation.

Most of the publications about DGN stimulation were performed in patients with neurogenic detrusor overactivity (NDO). In those studies, good results concerning bladder capacity and suppression of IDC are reported. Martens et al. performed DGNS with a needle electrode in eight spinal cord injury (SCI) patients with DO and reported a success rate of 100% in suppression of one or more IDC with conditional stimulation in neurogenic patients [33]. Opisso compared patient-controlled versus automatic stimulation with surface electrodes in 17 patients with NDO and reported that patient-controlled DGN stimulation is as effective as automatically controlled stimulation to treat NDO [34].

The aforementioned studies for DGN stimulation in neurogenic patients are studies with short-term DGN stimulation in a clinical setting. Recently, Opisso reported a study with subject-controlled DGN stimulation in 11 patients with NDO and urge incontinence at home during 3 days [35]. DGN stimulation was provided with surface electrodes placed either on the dorsal of the penis in males and on or close to the clitoris in females. Eight subjects completed the protocol. Higher bladder volumes with stimulation were seen. None of the subjects reported incontinence episodes on days 4 and 5. This study demonstrated that DGN stimulation in patients with intact bladder sensation is feasible and also suggested a carryover effect.

- DGN stimulation conceptually is an ideal way of neuromodulation since it stimulates afferent nerve fibers.
- All studies to date have been done in a research setting in mostly neurogenic patients.
- Only short time data exist with promising clinical results.

CONCLUSIONS

Peripheral neuromodulation is a proven and accepted treatment for OAB symptoms. PTNS is minimally invasive and not very expensive but it is time-consuming. Therefore, new techniques with implants are being explored. Experimental treatments like PN stimulation and DGN stimulation are promising, but they are still in an experimental phase and the clinical applicability still is limited.

Sacral Neuromodulation in the Treatment of Female Overactive Bladder Syndrome and Nonobstructive Urinary Retention

J.L.H. Ruud Bosch

Female voiding dysfunctions such as those related to overactive bladder (OAB) syndrome and nonobstructive urinary retention often are refractory to conservative management including drug therapy, behavioral therapy, pelvic floor muscle exercises, biofeedback, noninvasive or minimally invasive neuromodulation, and intermittent self-catheterization. Sacral nerve neuromodulation has proved to be valuable in these situations [1]. In 1997, the Food and Drug Administration (FDA) approved sacral neuromodulation for treatment of refractory urge urinary incontinence in the United States. Subsequently, approval was also granted for the treatment of urgency–frequency syndrome and for nonobstructive urinary retention. The labeling was later changed to include "overactive bladder" as an appropriate diagnostic category [2]. In spite of the fact that its mechanism of action is far from understood [3–6], the list of urological applications now includes refractory urgency incontinence, the urgency–frequency syndrome, nonobstructive urinary retention, interstitial cystitis, and chronic pelvic pain/painful bladder syndrome. The latter two are not FDA-approved indications, but the inclusion of interstitial cystitis is justified by the features of urinary frequency and urgency (with pelvic pain) [2]. The value of sacral neuromodulation (SNM) has now generally been recognized [7], and the therapy has been incorporated in guidelines and treatment algorithms such as those of the International Consultation on Incontinence [8].

MODE OF ACTION OF NEUROMODULATION

The precise mode of action of neuromodulation is unknown. Theoretically, its effects can be explained by modulation of reflex pathways at the spinal cord level [4,9]. However, supraspinal pathways seem to be involved as well [10]. Experimental work in animals, human volunteers, and patients has revealed that at least two mechanisms are important: activation of efferent nerve fibers to the striated urethral sphincter reflexively causing detrusor relaxation [11–13] and activation of afferent nerve fibers causing inhibition of the voiding reflex at a spinal and/or supraspinal level; pudendal nerve afferents seem to be particularly important for the inhibitory effect on the voiding reflex [14–16]. Pudendal afferent activity mapping during neurosurgical procedures of the sacral nerve roots has shown that the S1, S2, and S3 roots contribute 4%, 60.5%, and 35.5%, respectively, of the overall pudendal afferent activity, and it has also been shown that pudendal afferent distribution is confined to a single level (i.e., S2) in 18% of the subjects [17]. A lack of effect of S3 stimulation can therefore be expected in some subjects.

Detailed assessment of the sensory and motor response during lead placement seems to be important for long-term success [18]. This is possible with a two-stage procedure [19] using percutaneous tined lead placement under local anesthesia [20].

Paradoxically, neuromodulation also works in patients with urinary retention in the absence of anatomical obstruction. It has been postulated that neuromodulation interferes with the increased afferent activity arising from the urethral sphincter, restoring the sensation of bladder fullness and reducing the inhibition of the detrusor muscle contraction [21].

SELECTION OF CANDIDATES FOR PERMANENT SACRAL NERVE NEUROMODULATION

Sacral nerve neuromodulation (InterStim^{TM} therapy) differs from other types of neuromodulation by its continuous stimulation and close nerve contact. Its characteristic feature is the implantation of a pulse generator and an electrode lead stimulating one of the sacral nerves, mostly S3. Patients only receive a permanent implant if the preceding percutaneous nerve evaluation (PNE) test is successful or if the effects of the first stage of a two-stage implantation are favorable. In the first stage lead implantation (FS2S), only the definitive electrode is implanted but not the implantable pulse generator (IPG). A test stimulation, currently most often in terms of FS2S, still is the only way by which candidates for a permanent implant can be identified.

Test *Stimulation*

Early attempts to identify factors predicting the success of SNM have largely failed [22]. Later, Scheepens et al., in a multivariate logistic regression model, found that failure to respond to the test stimulation was associated with no previous surgery for intervertebral disk prolapse, longer duration of symptoms before IPG implant (longer than 7 months), neurogenic bladder (vs. no neuropathy), and nonobstructive urinary retention (vs. urinary incontinence), but not to patient age [23]. However, the odds ratios in this study were too low to justify the exclusion from testing of some patient categories. South et al. found a significantly lower percentage of responders to PNE in those older than 65 years. They also found that four or fewer incontinence episodes per day were significantly associated with PNE failure and that urodynamically proven detrusor overactivity in patients with refractory urgency incontinence does not predict the outcome of PNE [24]. Foster et al. suggested that patients with a greater decrease in 24 hour pad weight at initial test stimulation are more satisfied after the implant [25]. Psychiatric disorders also seem to be a predictor of failure [26]. Experienced implanters know that psychological factors constitute an important determinant of their personal bias in the assessment of the result of the test stimulation.

A true-negative test stimulation response of about 20% can be expected based on the neuroanatomical fact that pudendal afferents are confined to the S2 level only in 18% of all subjects [17].

The percentage of patients with urgency incontinence responding to traditional PNE was in the order of 61%–76% in reports of early adopters of this technique [27]. Later reports of traditional PNE quote lower success rates of about 50% [28]. This discrepancy may be related more to patient selection than to the technique of PNE itself. Recent experience with the two-stage implant using a tined lead has resulted in implantation rates of 77%–90% in patients with various indications [18,29,30]. Based on their experience with PNE testing or two-stage testing before tined lead implantation, van Voskuilen et al. [31] concluded that there is an approximately 20% false-negative rate of PNE testing only; however, in this report, the authors had a much lower PNE response rate (20%) than the 54% in a previous report from that institution [32]. One explanation for this difference might be the fact that, previously, 25% of the PNE responders actually underwent more than one PNE session.

Only a well-designed randomized controlled study between PNE and FS2S can confirm whether this is truly due to a better performance of the test.

Interestingly, a report on the results of sacral neuromodulation from a Swiss registry showed that only 74% of patients who tested successfully with traditional PNE went on to a permanent implant without further evaluation, as compared to 97% of patients, who tested successfully with the definitive lead (FS2S) [33]. This suggests that for some reason, either the patient or the investigator was not convinced by the positive PNE result. Of the 21 successful PNE patients who did not immediately proceed to permanent implant, 11 were additionally tested with the definitive lead before implantation was finally performed, but 10 others refused an implant for “personal reasons.” Again, one wonders whether bias toward the testing methods has been at play in this study.

It is clear that it remains difficult to eliminate investigator bias in the interpretation of test stimulation results, even in a randomized study design. And, maybe, this kind of personal view and interaction with the patient is necessary to filter out those individuals who are unsuitable for this type of treatment (like patients with a psychiatric problem) before a point from which return is difficult has been reached. Weil et al. have previously shown that a poor result after permanent implantation is found in 82% of patients with a history of psychological/psychiatric problems as opposed to 28% of patients without this kind of history [26]. In summary, although there seems to be widespread expert opinion that FS2S is better than PNE, there is no solid evidence for this. FS2S is probably considered superior because it results in a higher implantation rate. However, a higher implantation rate after testing is only acceptable if the “additional” patients that are identified with FS2S over PNE, i.e., the presumed false-negatives of PNE, have at least the same long-term outcome as the presumed true-positives of PNE. Unfortunately, there are as yet no conclusive studies that have addressed this issue.

In a mixed group of patients including nonobstructive retention and urge incontinence, Everaert et al. conducted a randomized trial comparing the one-stage and two-stage implant with the original nontined lead [34]. After 24 months of follow-up, they found a false-positive rate of 33% and 14% for the one-stage and the two-stage procedure, respectively. In this study, patients were randomized into one of the two groups only after a successful traditional PNE. Strikingly, all patients randomized to the two-stage implant subsequently passed the FS2S, showing that FS2S testing did not exclude any patients (i.e., presumed false-positives of traditional PNE) from a permanent implant. On the other hand, the difference in failures between the groups was almost entirely due to a difference in early failures (i.e., <3 months after the implant), i.e., 23.8% and 9.5%, respectively, for the one- and the two-stage implant. These conflicting results seem to imply that the sample size of the study was too small to draw solid conclusions. Obviously, a higher implantation rate is also associated with increased costs.

CRITICAL APPRAISAL OF THE RESULTS OF SACRAL NEUROMODULATION BY PERMANENT IMPLANTATION

Multiple case series and several randomized controlled studies of sacral neuromodulation have been reported. However, a completely satisfactory picture cannot yet be drawn in spite of more than 15 years of follow-up in some series. There are several problems with the interpretation of follow-up data of sacral neuromodulation. First, if complete follow-up of all implanted patients is available, the follow-up duration usually is short, and if the follow-up is longer, the percentage of patients that is accounted for is usually low. If those who are lost to follow-up are not in some way included in the final analysis, the reported success rates will be over optimistic and the estimated complication or revision rates will be too low. Second, the variable interpretation of the “>50% improvement over baseline in at least one of outcome measures equals success” criterion makes the comparison of various series difficult. For example, in urgency incontinence, some investigators would call a result successful, only if a >50% decrease in pad use *and* leaking episodes per day is achieved, while others would be satisfied if there is a >50% decrease in pad use *or* leaking episodes per day. Third, some implanters have challenged the “>50%” success criterion and have stated that >80% improvement is more relevant to the patient [35]. It is clear that many implanters have only proceeded with a permanent implant if at least a 75%–80% improvement was noted during test stimulation. This introduces a fourth problem with the evaluation of the clinical results of SNM: if a patient would have proceeded to implant on the basis of an improvement at test stimulation of 75% in one of the outcome measures and if the same patient would subsequently experience an only 55% improvement after 1 year of follow-up, she would still be considered a success in case the “>50%” success criterion is used. So, a report of success using categorical criteria with wide ranges can result in a gross overestimation of the benefits of the treatment. Unfortunately, only a minority of papers report the percentage of patients with urgency incontinence who become and remain dry or the percentage of patients with nonobstructive retention who do not need to self-catheterize at all after the implant. In patients with the urgency–frequency syndrome, it is even more difficult to define what constitutes “cure”: is it those who achieve a normal voiding frequency? But then, what is “normal,” eight or fewer voids?

REFRACTORY URGENCY URINARY INCONTINENCE (UUI)

The results of several case series with a total of 115 patients with urgency incontinence who were treated early in the experience with sacral neuromodulation have been summarized: after a follow-up duration of about 1–3 years, approximately 50% of patients with urgency incontinence without neurogenic causes demonstrate a more than 90% improvement in their incontinence after the permanent implant; 25% demonstrate a 50%–90% improvement and another 25% demonstrate a <50% improvement [27].

In a pivotal multicenter randomized study involving patients with refractory urgency incontinence, half of the patients in whom the PNE test was successful were implanted. Implantation was delayed for 6 months in the remaining patients, who received standard medical treatment and comprised the control group. The stimulation group demonstrated significantly better symptomatic results than the control group at 6 months follow-up [36]. There is a recent interesting report of a prospective randomized, multicenter study, evaluating sacral neuromodulation compared to standard medical treatment in subjects with mild symptoms of OAB. In this study, minimally invasive techniques, including the tined lead, were utilized in a contemporary population. Success was defined as a ≥50% improvement from baseline in average leaks/day. At 6 months, those with urgency urinary incontinence demonstrated a

71% success rate as compared to 47% success in those receiving standard medical treatment (p = 0.03) [37].

Detailed information on the durability of the effectiveness of SNM is relevant, especially in the light of the development of alternative options and the high costs of the treatment. Also, the determination of predictors of success remains important. Subgroups of refractory patients with urgency incontinence such as those following urogynecological surgery or urethrolysis seem to respond well to the treatment after short follow-ups [38,39].

Literature on the long-term results of SNM is relatively scarce. In a prospective Italian national register, 37 patients received an implant for urgency incontinence, and 17 had a minimal follow-up of 12 months. Out of 17 patients (59%), 10 were dry [40]. Three-year results have been reported by Siegel et al: a more than 50% reduction in leaking episodes per day was found in 52.8% of the implanted patients. Furthermore, 46% were considered dry after 3 years [41]. An analysis of a nationwide Swiss registry revealed that 27 of 71 implanted patients with urgency urinary incontinence failed (38%) after a median follow-up of 24 months [33].

There are five publications with a mean or median follow-up of at least 5 years [42–46]. Van Voskuilen et al. described the subjective long-term results in a mixed group of 149 patients (mainly women) [42]. The mean follow-up in the OAB group was 69.8 ± 41.6 months, but it was unclear how many patients had idiopathic urgency incontinence. The authors concluded that SNM gave a prolonged subjective benefit. Voiding diary parameters were not considered. The subject of the study by Scheepens et al. was the efficacy and safety of the two-stage implant technique in a group of 15 patients (also mainly women) with a median follow-up of 5.2 years [43]. Only seven patients had UUI. The number of leaks per day and the number of pads used per day decreased from 9.0 ± 4.3 and 5.0 ± 2.4 to 3.2 ± 3.4 and 1.0 ± 1.3, respectively. Elhilali et al. reported on 52 patients with mixed pathology, after a mean follow-up of 6.5 years. Only six patients had urgency incontinence and only one showed persistent improvement [44]. Van Kerrebroeck et al. reported the 5-year results of a postapproval study, which included patients from the original randomized controlled MDT-103 study, were reported [45]. Of the 96 patients with urgency incontinence, 65 completed the 5-year follow-up, and diaries were available from 54 patients (8 patients had been explanted); of these, 58% and 61% still had successful outcomes concerning the number of leaks per day and the number of pads used per day, respectively. In this evaluation, success was defined as >50% improvement of selected voiding diary parameters as compared to baseline. The percentage of patients who were dry is not reported.

Recently, the results of a prospective longitudinal single-center study with 60 women with idiopathic UUI refractory to conservative therapy who all passed the 5-year follow-up mark were reported by Groen et al. [46]. Five-year success rates of 50% and 53% for the number of leaks per day and the number of pads used per day, respectively, were found. However, only 9 (15%) of the 60 patients were fully continent after 5 years.

The studies with a long-term follow-up deal with patients who were implanted with the original nontined lead. Six-month follow-up in an early study of the tined lead showed results that seemed comparable to the experience with the original lead [47]. The medium-term outcome in patients implanted with the tined lead was reported in patients with refractory urgency incontinence by van Voskuilen et al. [31]. Treatment failure or lost to follow-up was seen in 29.6% after an average of 15.5 months. Sutherland et al. reported on their 11-year experience. The 104 patients in the analysis represent only 44% of the implanted patients between 1993 and 2004. The reasons for not consenting are unknown for what seems to be an exceptionally high percentage of patients not consenting (56%) to a retrospective chart analysis. With a mean follow-up of 22 (range 3–162) months, sustained subjective improvement was more than 50% in 69% of the urge incontinent patients. Of these leads, 47.1% were tined [6]. A recent report of long-term follow-up in a series of 217 patients included more than 10% of patients who were implanted with the tined lead; after a mean follow-up of 47 months, about 70% of the patients with urgency incontinence were a success (i.e., demonstrated ≥50% improvement in leaks/day). However, only 20% were cured, meaning dry [48].

A cure from refractory urgency incontinence has now been reported in 15–20% of patients after a follow-up of 4–5 years [46,48]. A 100% improvement may seem demandingly high as a criterion of success, but is relevant considering the high costs of the therapy and the availability of newer alternatives such as onabotulinumtoxin-A injections [49]. Watanabe et al. showed that 3-year cumulative cost estimates of sacral neuromodulation were about twice as high as those for intradetrusor injection of onabotulinumtoxin-A [50]. The important issue of the patient perspective has recently been surveyed by Balchandra and Rogerson. In their survey, 74% of the 50 women with a mean age of 62 years chose onabotulinumtoxin-A intradetrusor injections over SNM after detailed counseling on the two treatment options ($p < 0.003$) [51].

In a study of 20 patients who had discontinued onabotulinumtoxin-A intradetrusor injections, 14 were implanted with an Interstim system after >50% improvement was achieved in the test phase. After 1 year of follow-up, the improvement was sustained in 11 subjects (55%), and 5 of these had experienced a >90% decrease in leaking episodes [52]. So, sacral neuromodulation may be an option after onabotulinumtoxin-A intradetrusor injections.

Another issue that should be considered is the natural history of urgency urinary incontinence or OAB-wet: Irwin et al. have shown that of women who were classified as OAB-wet in 1992, 49% were dry in 2003, indicating that with time there is a certain percentage of spontaneous resolution, or at least a fluctuating presence of the condition. Therefore, a certain percentage of the improvements seen with treatment may be due to fluctuating symptoms or spontaneous resolution [53].

URGENCY–FREQUENCY SYNDROME

In a multicenter randomized study involving patients with urgency–frequency syndrome, half of the patients in whom the test stimulation was successful were implanted [54]. Implantation was delayed for 6 months in the remaining patients, who received standard medical treatment and comprised the control group. The stimulation group demonstrated significantly better symptomatic results than the control group at 6 months follow-up.

Surprisingly, only a few reports exist on long-term results of SNM in urgency–frequency syndrome. Siegel et al. [41] reported that 2 years after implantation, 56% of the patients with urgency–frequency syndrome showed a more than 50% reduction in voiding frequency. Elhilali et al. reported persistent improvement in 10 of 22 (45%) patients with urgency–frequency syndrome after an average follow-up of 6.5 years [44].

The 5-year results of a postapproval study, which included patients from the original randomized controlled MDT-103 study, were reported [45]. Success was defined as >50% improvement of selected voiding diary parameters as compared to baseline. Of the 25 patients with urgency–frequency syndrome, 5-year follow-up diaries were available from 11 patients (7 patients had been explanted), and 40% of these still had a successful outcome concerning the number of voids per day. The average number of voids had decreased from 19.3 to 14.8, but it is unclear whether any patient experienced normalization of voiding frequency [45].

The recent report of Peeters et al. showed that after a mean follow-up of 47 months, 68% of patients with urgency–frequency syndrome demonstrated ≥50% improvement. However, only 33% were cured, meaning no urgency and a normal daytime frequency [48].

NONOBSTRUCTIVE URINARY RETENTION

Jonas et al. reported that 68 of 177 nonobstructive retention patients responded to traditional PNE with a greater than 50% improvement. Of the implanted patients, 69% eliminated catheterization at 6 months follow-up, and an additional 14% had a greater than 50% reduction in catheterization volume. At 18 months follow-up, catheterization was completely eliminated in 58% of 24 evaluable patients [55]. Swinn et al. reported a 68% success rate with PNE in 38 women, mostly with Fowler's syndrome [21]. The same group reported their long-term results in 60 implanted women. After a mean follow-up of 48 months, 72% voided spontaneously and 50% did not need to perform self-catheterization [56]. Another group reported their results in 20 implanted women. After a mean follow-up of 41 months, 86% voided spontaneously and 55% did not need to perform self-catheterization [57].

The 5-year results of a postapproval study of the original randomized controlled MDT-103 study were recently reported. Success was defined as >50% decrease in the number of catheterizations per day as compared to baseline. Five-year follow-up diaries were available from 22 of 31 patients with nonobstructive urinary retention (1 patient had been explanted), and 58% of these still had a successful outcome. However, the percentage of patients that did not have to catheterize at all was not reported [45].

Kessler and Fowler reviewed the results of SNM for urinary retention and found that the success rate ranged between 55 and 100% after a follow-up duration of 43 and 15 months, respectively [58]. Recently, Peeters et al. reported on 93 patients with nonobstructive urinary retention: after a mean follow-up of 47 months, 58% of the patients did not need to catheterize anymore [48].

They also found a higher long-term success rate in patients implanted for Fowler's syndrome than in those with idiopathic retention, with 62.5% and 53%, respectively, not needing to self-catheterize.

In summary, a more than 50% reduction in the number of catheterizations is found in 58%–86%. The cure rate, that is, the percentage of patients not needing to catheterize at all, is around 50%–58% after 41–48 months of follow-up.

INTERSTITIAL CYSTITIS

Several authors performed permanent implantations of the InterStim^{TM} device for treatment of interstitial cystitis. Some investigators report good results with up to 75% improvement in symptoms [59–61], including a 20% "cure" rate [60]. However, follow-up in these studies was short (range 5.6–14 months). Berman et al. could not confirm these results [62]. Only 2 of 13 patients (25%) were pleased or delighted with the InterStim device. A randomized crossover trial of sacral versus pudendal nerve stimulation (PNS) (with the InterStim system) for interstitial cystitis indicated that overall symptom reduction with PNS might be somewhat better than with sacral nerve stimulation (59% vs. 44%; $p = 0.05$) [63]. Of those with a permanent implant, 13 of 17 chose the pudendal lead. The 17 patients were followed for 6 months: 3 did not complete follow-up visits, and in the remaining patients, the number of voids decreased by 41% for PNS and 33% for SNS (statistically not different).

Battery longevity in a Medicare population after sacral neuromodulation was reported by Cameron et al., who noted that 11 of 19 batteries implanted for interstitial cystitis were removed and the odds of explantation in interstitial cystitis patients were 10.5 (95% CI: 3.9–28.4) [64].

The limited evidence in interstitial cystitis patients seems to indicate that sacral nerve neuromodulation leads to an initial symptom improvement but is not very successful with longer follow-up.

ADVERSE EVENTS

The necessity to reposition the electrode after migration was reported in about 20% of patients in the early experience with SNM [32,65]. Pain at the site of the pulse generator or the lead or in the leg is the most frequently reported problem. Siegel et al. reported adverse events for 219 InterStim-implanted patients [41]. The majority of events observed were pain at the stimulator site (15.3%), new pain (9%), pain at the lead site (5.4%), suspected lead migration (8.4%), infection (6.1%), transient electric shock (5.5%), and adverse changes in bowel function (3%). Dasgupta et al. also reported a high overall adverse event rate of 51.6% [66].

In a review of randomized trials and case series, Brazzelli et al. noted a 33% surgical revision rate in 855 patients, with pain at the stimulator site being the most common problem, accounting for 25% of the surgeries [67]. Van Voskuilen et al. reported a surgical revision rate of 48.3% (excluding pulse generator replacements) after an average follow-up of 64.2 months [42]. During a 7-year study period, 26 surgical revisions (including 8 explants) had to be performed in 55 women who had been implanted for refractory voiding dysfunction (47.3%) [68].

Sutherland et al. reported on their 11-year experience in 104 patients. In this population, 47.1% of the leads were tined [6]. A 53% adverse event rate was reported. Notably, the adverse event rates associated with tined and nontined leads were 28% and 73%, respectively. However, the follow-up duration was quite different. The average follow-up of the tined lead versus the nontined lead group is approximately 1–1.5 years versus 5–5.5 years. This difference can at least partly explain the difference in adverse event rates. The tined lead is not free from complications and lead migration has been reported in 2.1% [69], but this is less than the 8.4% suspected lead migration rate reported with the original lead [41].

CONCLUDING REMARKS

Neuromodulation can be very beneficial for some patients with an OAB syndrome or nonobstructive urinary retention and should be considered before applying more invasive, nonreversible treatments. However, the durability of the initial success is probably overrated in most reports. The cure rate in patients with refractory urgency incontinence is around 15%–20% at 4–5 years of follow-up [46,48]. In patients with nonobstructive urinary retention, the cure rate at 3.5–4 years is about 50%–58% [48,56,57]. It is difficult to define cure in patients with the urgency–frequency syndrome; a normal daytime voiding frequency seems to be achievable in about a third of the patients [48]. The published reoperation rate approaches 50% after an average follow-up of 5 years [42]. The effect on the quality of life is unclear [7]. Unfortunately, the true cost/benefit ratio of this expensive type of treatment is not known [35].

It is still unclear how best to choose patients for this procedure, since no predictors of success have been identified. Technical advances such as the use of the tined lead, the two-stage implant, the smaller InterStim II pulse generator, buttock placement of the pulse generator, and the less invasive partially percutaneous technique seem to have decreased the necessity for revision [28,70]. However, higher success rates with the definite implant are not to be expected with these technical modifications, provided that the sacral nerve is stimulated adequately when using the older technique.

49 Injectable Bulking Agents in the Treatment of Female Stress Urinary Incontinence

Brian J. Linder, Philip Wanzek, and Deborah J. Lightner

INTRODUCTION

A multitude of options exist for the management of female stress urinary incontinence (SUI), such as pelvic floor muscle training (PFMT), urethral suspension procedures, urethral slings, and urethral bulking agents [1–3]. Careful patient education regarding the etiology and natural history of SUI as well as the physiology of urinary storage and voiding is extremely helpful in setting shared goals with the patient regarding all management options. Current guidelines recommend, at a minimum, a focused history and physical exam; an objective demonstration of SUI and urinalysis; and an assessment of postvoid residual, with additional diagnostic testing (urodynamic evaluation, cystoscopy, imaging, etc.) being utilized on a case-by-case basis [1–3].

For bothersome SUI, a shared patient decision on which management strategy to pursue is made after thorough discussion of the many options available and their attendant risks and benefits. Presently, a first-line approach with noninvasive treatment via behavioral management and PFMT may allow some women to avoid surgical intervention, albeit, via postal surveys at 15 years, the effectiveness of this management does not appear sustainable [4].

For many patients choosing bulking agents, a desire for a simple in-office injection technique with immediate, albeit not permanent, result may be paramount. Others, based on realistic goals, choose urethral bulking having undergone one or more prior procedures with less than a satisfactory outcome and are not interested in enjoining more invasive procedures. Some patients may not be candidates for other procedures due to fragility or medical comorbidities. Less commonly, patients may have a poorly coaptable, fixed urethra [5], i.e., a “pipestem” urethra [6], therein reducing the efficacy of procedures dependent upon the augmentation of closure mechanisms by reducing urethral hypermobility with stress events.

INDICATIONS

Bulking agents are used where bothersome urinary incontinence results from poor intrinsic sphincter function, often quantified by the determination of the abdominal leak-point pressure or maximum urethral closure pressure (MUCP) [7]. Notably, there is a lack of high-quality evidence correlating the results of urodynamic studies with treatment outcomes for patients with SUI [8,9]. As such, complex urodynamic-derived criteria are generally not required prior to the use of bulking agents. The determination of the postvoid residual volume, however, is recommended prior to the use and reinjection of bulking agents [9], both diagnostically and to reduce adverse events, as the application of bulking agents in the setting of an elevated postvoid residual may lead to outlet obstruction and overflow incontinence [10].

Bulking agents may be used as primary treatment and, importantly, do not hamper the subsequent use of surgical procedures when and if necessary to complement sphincteric competence [11]. Notably, bulking agents for female SUI have the uncertain honor of having more English-language review articles since 2000 [12–24] than primary RCTs [25,26–31].

In addition to use as a primary treatment, several reports support injection of bulking agents as an effective adjunct for many difficult clinical scenarios, including secondary application following failed surgical procedures [32–34] and following radical pelvic surgery in both men and women [35,36], in patients with spinal cord injuries [37,38], or for continent stomas [39] that lack the desired level of continence due to insufficient closure pressures. As with use in a primary setting, large high-quality studies of bulking agents in the aforementioned challenging situations are lacking. Additionally, effective soft-tissue bulking has been reported in pediatric vesicoureteric reflux [40–43], fecal incontinence [44–49], cosmetic procedures [50,51], and gastroesophageal reflux [52].

MECHANISM OF ACTION

The urinary sphincter is a complex and naturally complementary closure mechanism to the varying pressures placed across the pelvic floor. Coaptation of the urethral lumen allowing for a watertight seal involves the physical properties of the intrinsic softness of the mucosa [5], supportive connective tissue, normal vascularity [53,54], neural integrity, and adequate function of surrounding smooth and striated muscle to provide resistance to these variable intra-abdominal forces. The voluntary sphincters are necessary for active continence; hence, strength training these voluntary muscles with pelvic floor muscle contractions [55,56] allows for heightened closure pressures during momentary and nonsustained increases in abdominal pressure, as occurs with coughing, sneezing, and other Valsalva activities.

Bulking agents work by increasing resistance to intra-abdominal forces via the soft-tissue filler properties of the injectable agent [57]. The capacity to bulk soft tissue is inherently limited. Hence, improvement of continence may be limited if the degree of incontinence is severe. Poor tissue compliance may not accommodate sufficient soft-tissue fill for complete continence. Though only case reports exist, poorly coapting soft tissues due to neural damage, in postprostatectomy incontinence [36,58–61] or stomas, may achieve effective soft-tissue fill with a bulking agent.

Injected autologous cells of skeletal muscle (muscle-derived cells [MDC]) may provide an additional benefit to soft-tissue bulking including a dynamic element of muscular contraction and potentially enhanced resting tone.

HOW HAVE RESULTS BEEN QUANTIFIED?

Several comparative trials have measured the efficacy using the Stamey Urinary Incontinence Scale [62], which is likely associated with a poor discrimination index [63] to detect changes in continence (i.e., integrals are broad, as in 1, leakage with vigorous activity, versus 2, leakage with minimal stress). More recent trials have included more sensitive and appropriate measures of change in continence, including pad tests, validated questionnaires, and patient perception of effectiveness [64].

Most comparative trials are noninferiority trials [65] with their inherent limitations and used Contigen^{TM} (no longer available) as the comparator.

Current literature does not demonstrate any significant difference in efficacy or complications between currently accepted bulking agents [3]. Bulking agents' effectiveness tends to decrease over time. Anticipated efficacy for patients treated with collagen without concomitant prolapse treatment has been reported to decline over time, from 48% at 12–23 months to 32% at 24–47 months [66]. A recent systematic review of response rates at 12 months with experienced surgeons approached 30%–40% dry, with twice that percentage dry/improved. Unfortunately, none of the current bulking agents have proven durable; several of the RCTs are notable in that they were designed to end at 12 months after the last injection.

Using all measures, bulking agents are less effective and less durable than other procedures but remain less invasive with lower complication rates [67].

WHICH BULKING AGENT TO CHOOSE?

Each of the available bulking agents is similar in benefits/risks/burdens [3]. In an unusual trial of multiple agents, a 12-month analysis of over 800 cases of urinary transurethrally applied glutaraldehyde-cross-linked collagen (n = 312), nonanimal stabilized hyaluronic acid/dextranomer (NASHA/Dx) (n = 54), ethylene vinyl alcohol (EVOH) (n = 104), and polyacrylamide hydrogel (n = 44) demonstrated that the objective and subjective measures were similar for each group, with negative pad tests in over 70% of these women [68]. For most agents, the published prospective randomized trials have been industry sponsored and therefore limited to one or two randomized trials. Much of the other referenced literature details durability and adverse events.

However, the technique of bulking agent injection requires a measured degree of expertise. Given that each bulking agent has characteristics specific to its application, most centers choose a bulking agent and become facile with that agent. Impaired durability of the bulking agents is a greater challenge than current safety issues.

Currently, the availability of injectable agents varies considerably around the world from country to country due to differential regulatory environments. As of 2016, commercially available agents include the following:

- *Polydimethylsiloxane macroparticles suspended within a bioexcretable carrier hydrogel of polyvinylpyrrolidone* (Macroplastique^{TM}, Cogentix Medical, Minnetonka, MN).

  Requiring a pressurized injection system, 247 females with intrinsic sphincter deficiency in a multicenter study were randomized 1:1 and treated with Macroplastique versus Contigen® serving as a control. At 12 months, the cure/dry rate was statistically better at 36.9% for those treated with Macroplastique versus 24.8% in the control group [28]. In a rare study following a study group out to 24 months, 33 of 38 of the patients achieving dry/continence at 12 months remained dry at 24 months. An additional 12 of 29 patients, who were judged improved at 12 months, were dry at 24 months [69]. The Macroplastique Implantation Device, a specialized pressured syringe and applicator, allows for outpatient transurethral cystoscopic injection under direct vision. Sterilization of the reusable injector system requires enzymatic cleaning, disinfection, and autoclaving, which may not be available within the outpatient or clinic setting.
- *Calcium hydroxylapatite (CaHA)* (Coaptite^{TM}, Boston Scientific Corp., Natick, MA).

  A multicenter RCT of 296 women, also using the poorly discriminatory Stamey Urinary Incontinence Scale to assess outcomes, found that 63.4% of patients injected with CaHA achieved an improvement of one Stamey score compared with 57% of patients injected with Contigen^{TM} [70]. The material is injected with a disposable 21-gauge needle under cystoscopic guidance and readily adapted to the outpatient or clinic setting.
- *Zirconium-coated Carbon beads* (Durasphere® EXP, Coloplast Corp, Minneapolis, MN).

  In a noninferiority trial with Contigen^{TM} as the comparator, Durasphere® achieved a nonstatistically significant improvement of one or more Stamey grade in 80% of the 61 women treated, compared with 69% of the 68 women treated with Contigen^{TM} [31]. The initial reports utilized a needle system that was cumbersome; the newer formulation ("EXP") and better needle design have facilitated these injections in the outpatient setting.
- *Polyacrylamide hydrogel (PAHG)* (Bulkamid^{TM}, Contura, International A/S, Soeborg, Denmark).

  Periurethral injections of Bulkamid^{TM} appear safe and effective in the short term in two single-arm 12-month studies of 135 and 82 women demonstrating objective improvement on pad tests [71] and in subjective measures (visual analog scales, validated questionnaires) [71,72]. A recent multicenter RCT of Bulkamid^{TM} vs. Contigen^{TM} in a 2:1 randomization demonstrated noninferiority of Bulkamid ^{TM} to Contigen^{TM} with 47.2% and 50% of patients treated with Bulkamid^{TM} versus Contigen^{TM} achieving zero incontinence episodes, respectively, and 77.1% versus 70% of patients treated with Bulkamid^{TM} versus Contigen^{TM}, respectively, cured/improved.
- *Porcine dermal implant* (Permacol^{TM}, Covidien plc, Dublin, Ireland).

  In a 6-month RCT of 50 women, Permacol^{TM} formulated for injection was compared with Macroplastique^{TM} again using the weakly discriminating Stamey Urinary Incontinence Scale coupled with a validated questionnaire. They reported that 64% and 60% of the Permacol-treated patients achieved improvements in these respective outcome measures versus 46% and 42% improving in the Macroplastique^{TM} group [30].

NOT AVAILABLE

- *Glutaraldehyde-cross-linked bovine collagen (Contigen^{TM})* has been the standard against which other agents have been compared; unfortunately, the bovine collagen is no longer available. Furthermore, the product is immunogenic requiring a negative skin testing 30 days prior to bulking agent injection.
- *Autologous fat* should no longer be used due to ineffectiveness against injected saline

demonstrated in a randomized trial [73]. A fatal pulmonary embolism [74] and a fat embolism syndrome [75] argue strongly against its use; of note, the fat embolism syndrome was associated with an injection with 14G needle using a periurethral approach. Of note, autologous fat remains widely used in cosmetic procedures and purportedly retains 60% of its bulk over time. This result has not been translatable to safe or efficacious use in urinary incontinence.

- *NASHA/Dx (Zuidex*^{TM}): With a high rate of pseudoabscess formation precluding its use [27], *Zuidex* has been used with [27] or without [76] the Implacer device, a noncystoscopic transurethral injection device. However, the Deflux^{TM} formulation of NASHA/Dx is effective and safely used in pediatric vesicoureteric reflux.
- *EVOH copolymer (Uryx*^{TM}): Uryx is used much more extensively in vascular and interventional studies in an alternative formulation; it has also been studied as a potentially reversible compound injected into the vas deferens [77] or fallopian tube [78] for sterilization. It was withdrawn from the SUI marketplace due to frequent reports of urethral erosion of the material [79].
- *Polytetrafluoroethylene (Polytef*^{TM}): Polytef was associated with migration in animal studies [80] and is no longer used in routine clinical practice [81].

TECHNIQUES

Bulking agents have been injected periurethrally (peristomal), transurethrally (transluminally), or combined [64], in the midurethra [27] and at the bladder neck [82], both in retrograde [83] and antegrade fashion [84], and with cystoscopic guidance in most [85], but not all [86]. Standardization of techniques has hampered comparison of results.

Achieving higher "maximum squeezing" opening pressure correlates with improved continence after bulking agents. It has therefore been suggested that agents should be injected on the luminal side from the sphincter and at the high-pressure region of the sphincter [57].

A bulking agent theoretically achieves a gradual increase in the central filling of the urethral soft tissue, as may be measured by an improvement in MUCP [57,68]. Increasing volume of the injected bulking agent would subsequently result in decrease in luminal closure pressure if the bulking agent either overbulked the region [47] or conversely extravasated. Notably, success rates have been reported to decrease with an increased number of injection sites, likely due to extravasation [87]. Injection of the material, therefore, should be slow and deliberate in order to maximize fill and reduce disruption of the fragile soft tissue. Sequential injections are preferable to bursting the soft-tissue *envelope* created by the bulking agent. Therefore, it may be useful to think of reaching a "sweet spot" with the volume injected: too little is ineffective at raising the intraluminal closure pressures, and too much will burst the envelope containing the bulking agent.

Transurethral injections directed nearer to the bladder neck may be associated with less urinary retention compared with periurethral injections as is reported in some studies comparing methods. It has been theorized that the greater volume reported in most comparative trials of the periurethral injection may be an associated cause [88]. Others have suggested that a luminally placed bulking agent might allow for higher degrees of soft-tissue creep (i.e., resistance to deformation by stressors) than a periurethral application, thereby implying higher efficacy of a transurethrally placed agent [88]. Others report no statistical difference between the effectiveness of the periurethral versus transurethral approach to injection [88,89].

In the transurethral technique, the bulking agent may be injected at the bladder neck or the midurethra under cystoscopic guidance. There is insufficient comparative data to support bladder neck versus midurethral injection. In the transurethral cystoscopic approach, the urethral mucosa is punctured distal to the chosen injection locale in the urethra. Prior to the puncture, the urethra and bladder are inspected and the scope is then withdrawn to the distal urethra. The middistal portion of the urethra is punctured with the bevel of the needle toward the lumen at a 30°–45° angle. The needle is transluminally advanced into the submucosa, but not to the muscularis. The angle is subsequently dropped parallel to the path of the urethra, and the needle is advanced approximately 1 cm within the submucosal layer with slow deliberate injection of the material aided by visual deformation of the tissues and halting further injection particularly if blanching of the mucosal vessels is observed.

The bulking agent is more effective in a circumferential distribution [90]. Submucosal hydrodissection with lidocaine may be performed prior to injection [91] to reduce discomfort and to prepare the envelope for the agent. Once the injection is completed, the needle is held in position for several seconds prior to withdrawal, in order to allow for equilibration of pressures within the receiving soft-tissue envelope and to reduce extravasation from the needle site [91]. While failure rates have been reported to increase with the number of puncture sites [83], presumably due to the loss of the bulking agents through these punctures, several industry-recommended techniques include three-site injections (e.g., Macroplastique).

Contraindications to the use of a bulking agent in an appropriately selected patient include an active urinary tract infection or known hypersensitivity to the agent or any of its components. Bulking agents have been successfully and safely injected in fully anticoagulated patients, albeit with a theoretical concern for an increased risk of ongoing hematuria or urinary retention in the setting of a periurethral hematoma (personal experience).

COMPLICATIONS

Currently, available bulking agents have an acceptably low rate of acute and chronic complications. The most common adverse event is temporary urinary retention with major adverse events being rare [62,63,84]. Acute urinary retention has been reported in up to 24% of patients in a study of Durasphere and thus deserves mention during patient counseling. Additionally, it should be noted that retention in this setting is transient, for instance, lasting 7 days or less in most series [24,63]. Other adverse events that may be commonly encountered include postoperative dysuria, hematuria, uncomplicated urinary tract infection, and de novo urinary urgency, which typically resolve with conservative management [62,63,92,93]. Aspiration or incision and drainage of the injected agent is associated with 100% return of the patients prior sphincteric incontinence [94].

A few specific long-term complications that are quite rare, typically reported as single cases or small series, merit consideration as well. Urethral prolapse, potentially from disruption of support between the urethral mucosal and muscle wall with urethral bulking, has been reported [95–99]. Periurethral masses, variously described as periurethral pseudocyst [100] or sterile pseudoabscess [48,75,76,100–105], may be large and symptomatic and are associated with outlet obstruction [106] and/or pain [75]. Treatment of these lesions with aspiration [94] is associated with symptomatic pseudoabscess reoccurrence and thereby may require definitive transurethral, transvaginal, or retropubic incision and drainage [76]. These masses, if draining spontaneously into the urethral lumen, might progress to a de novo urethral diverticulum [107,108]. Extremely rare is a single case report of an infectious abscess [104]. As several agents require high-pressure injector systems, particle migration into local and distant lymph nodes may occur [109] and be visibly confirmed if the bulking agent is able to be imaged. Embolization may also occur, though only autologous fat has been reported to result in pulmonary embolism [75] and death [74]. Bulking agents can be inadvertently injected into the periurethral venous plexus.

All bulking agents could be erosive, resulting either from a property of the injected agent [110] or of the surrounding tissue [111,112] and may result in the extremely rare complication of fistula formation. Transvaginal incision and drainage of a pseudoabscess carries this theoretical risk.

Adverse events have also been reported outside of the urologic and gynecological literature, such as in plastic surgery series, but are likewise rare [113,114].

IMAGING

Bulking agents will cause deformation of the normal tissue planes on imaging [115,116]. These may be radiographically opaque (Durapshere™, Coaptite™). Of greater concern is the normally functioning bulking agent occasionally misinterpreted as a complex soft-tissue mass suggestive of malignancy, periurethral abscess, or urethral diverticulum. There are no known reports of mutagenicity or malignancy in association with any of the bulking agents. If a history of a bulking agent injection is unknown, misdiagnosis of a bulking agent as a diverticulum or soft-tissue fluid collection is not uncommon [117].

RESEARCH

The reconstructive and regenerative medicine literature includes multiple reports of other soft-tissue bulking agents. Thus, the nonurological literature may be instructive in the development of other agents for the treatment of SUI [118,119]. As an example, polymethylmethacrylate microspheres in miniswine were found to be safe at necropsy [120]; however, subsequent human studies report complications in soft tissues [121].

The pelvic floor specialist has been told to look for a durable bulking agent. However, this is in contradistinction to much of the cosmetic literature that is searching for temporary soft-tissue fillers, such as poly-l-lactic acid or hyaluronic acid fillers. The cosmetic and plastic surgeons work under the assumption that all such soft-tissue agents will be temporary due to progression of the soft-tissue changes occurring with aging [93]. Although these age-progressive soft-tissue changes have not been quantified in the female continence mechanism, perhaps changes in the host tissue relate to the nondurability of the effect of bulking agents used for incontinence. Evaluation of longitudinal changes in the abdominal leak-point pressure in a cohort population with SUI not electing treatment might alter our expectations for an agent's durability and for planned retreatment.

Autologous cells: Given the relatively poor efficacy and durability with bulking agents as compared to other invasive therapies for SUI, autologous cells represent a promising therapy. Unfortunately, early work in this area was compromised by a lack of research integrity [92]. The rapidly expanding regenerative medicine literature will potentially lead to advances in this field for SUI [122]. Incontinence studies using autologous MDC are early, but promising. Obtained by needle biopsy of the quadriceps femoris muscle and subsequently expanded and injected into the urethral sphincter, MDC injection was safe in 8 women followed for 18 months. A dose–response curve was suggested in 8 of 9 patients in the high-dose group reported zero to one leaks in a 3-day diary compared to 5 out of 15 in the low-dose group [123]. A 2-year follow-up of 16 women injected with autologous upper-arm MDC also reported reasonable safety, but efficacy again suggested a dose–response effect with a modicum of efficacy (questionnaire based). Many of these studies are not designed to determine if the injected muscle cells are viable or functional [124] that leads to the hypothesis that these interventions exert their favorable effects simply by providing passive tissue bulking [125]. Other studies are underway in the United States. (https://clinicaltrials.gov. Search bulking agents, wherein there are nine open trials, accessed July 23, 2014.)

FUTURE RESEARCH

Future areas of research regarding urethral bulking may include the following:

1. Improved reporting
   a. Standardization of patient populations and outcomes such that bulking agents may be accurately compared with each other and with other treatment modalities
   b. Kaplan–Meier curves for bulking agents beyond 12–24 months
2. Large cooperative reports of the use of bulking agents in alternative clinical situations, such as
   a. Sphincteric urinary incontinence due to spinal cord injury or pudendal injury
   b. Postprostatectomy incontinence with either anastomotic regions or resected areas that retain both tissue compliance and expandability
   c. Continent stomas or neobladder anastomotic regions that lack effective seal for achieving dryness
3. High-quality studies on MDC to establish their durability and potentially enhanced continence beyond a pure tissue bulking agent

50 Use of Botulinum Toxins in the Management of Female Voiding Dysfunction

David Ginsberg and Ellen Goldmark

INTRODUCTION

Botulinum toxin (BoNT) was initially FDA approved for the treatment of strabismus in 1989. Over time, its use has expanded for the treatment of a variety of multiple conditions, including migraine headaches, limb spasticity, cosmetic surgery, muscular dystonia, and lower urinary tract dysfunction [1]. The first urological application for BoNT was reported in 1988 for the treatment of detrusor sphincter dyssynergia (DSD) [2]. In 2000, BoNT serotype A (BoNT-A) was described as being an effective treatment for patients with detrusor hyperreflexia secondary to spinal cord injury (SCI) with urinary incontinence between intermittent catheterization [3]. It was not until over a decade later, in August 2011, that BoNT-A finally received FDA approval for the treatment of urinary incontinence due to neurogenic detrusor overactivity (NDO) in patients who had an inadequate response or were unable to tolerate anticholinergic medications [4,5]. Shortly thereafter, in January 2012, the FDA approved the use of BoNT-A in patients with overactive bladder (OAB) with symptoms of urge urinary incontinence (UUI), urgency, and frequency in adults who have an inadequate response to or are intolerant of an anticholinergic medication [6].

Off label, it is used in women with frequency/urgency and no evidence of DO, interstitial cystitis/painful bladder syndrome (IC/PBS), and DSD. The use of BoNT-A for the treatment of a variety of female urological conditions has provided an alternative to major reconstructive surgery in patients with NDO as well as relief from bothersome OAB symptoms in women who have failed medical therapy.

Biology and Mechanism of Action

Clostridium botulinum is a Gram-positive anaerobic bacterium, whose strains produce seven immunologically distinct neurotoxins (types A–G). It was first isolated by van Ermengem in 1897 [7]. Types A and B have been used to treat medical conditions, with type A being used most often as it is relatively easily obtained and stable. The neurotoxin component is synthesized as a biologically inactive single-chain polypeptide activated by cleavage of the polypeptide chain into a 100-kDa heavy chain and a 50-kDa light chain linked by a disulfide bond [8,9]. There are a variety of type A botulinum toxin products available; these products are not equivalent and the doses are not interchangeable. Table 50.1 summarizes what is currently commercially available in various countries around the world. OnabotulinumtoxinA (Botox, Allergan, Irvine, CA) is the only botulinum toxin product approved for use in the lower urinary tract in the United States.

Under normal circumstances in striated muscle, each muscle fiber is innervated by a single motor neuron at a site near the middle of each muscle fiber. This is termed the motor end plate. Within each nerve terminal are cystoplasmic vesicles containing Ach transmitter molecules. The Ach collects within clusters of these synaptic vesicles and each vesicle aligns with a patch of dense material forming an active zone. At the active zone in response to a propagated neural impulse, vesicles fuse with the plasma membrane resulting in the release of the Ach transmitter molecules into the synaptic cleft. The Ach diffuses across the synaptic cleft, binding to and stimulating the postsynaptic Ach receptors on the muscle cell. This results in a muscle contraction [10]. Three intracellular membrane-associated proteins are required for the binding of Ach-filled vesicles to the presynaptic active zone and exocytosis of Ach into the synaptic cleft: synaptobrevin, synaptosomal-associated protein 25 (SNAP-25), and syntaxin. The three proteins and the synaptic vesicle form the soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) complex [11].

Both the light chain and the heavy chain of the BoNT molecule have specific roles in creating its physiological effect. After injection, BoNT is taken up by nerve cells via the heavy portion of the molecule. Its heavy chain is involved in the binding of the neurotoxin and in the transportation of the neurotoxin into the neuronal cytosol (endocytosis). Once the molecule is intracellular, its light chain is responsible for the cleavage of the intracellular protein SNAP-25 that prevents formation of the SNARE complex and thus prevents binding of the synaptic vesicle to the cell membrane and release of Ach [12–14]. Without the release of Ach into the synaptic cleft, there is no muscle contraction.

BoNT-A Use in Neurogenic Detrusor Overactivity

NDO refers to the urodynamic finding characterized by involuntary detrusor contractions (IDCs) during the filling phase of urination, which may be spontaneous or provoked, due to a relevant neurological condition [15,16]. It is critical that patients with NDO maintain low bladder pressure during storage and voiding to prevent upper tract complications, recurrent urinary tract infection (UTI), bladder stones, and vesicoureteral reflux (VUR). Anticholinergics have traditionally been the mainstay of treatment in patients with NDO; however, these medications may cause and/or exacerbate dry mouth, as well as constipation, already an issue in this patient population [11]. Additionally, many patients continue to experience urinary leakage despite maximum medical therapy. The treatment goal of using BoNT-A in patients with NDO due to SCI is often to cause urinary retention. In such patients, initiation of intermittent catheterization is necessary to effect bladder emptying. The first paper to demonstrate success of onabotulinumtoxinA in patients with NDO was published by Schurch et al. in 2000. Despite maximum medical therapy, 21 patients with SCI and NDO with incontinence were found to have a significant increase in maximum cystometric capacity (MCC) and a mean decrease of maximum detrusor pressure following injection of 300 units of onabotulinumtoxinA. Incontinence was resolved in 17 of 19 patients and the clinical effect was still present at 9 months in the 11 patients who were still being followed [3].

Table 50.1 Different Forms of Botulinum Toxin (Serotype A) in Clinical Use

	OnabotulinumtoxinA	**AbobotulinumtoxinA**	**IncobotulinumtoxinA**
Commercial name	Botox® (Allergan, Irvine, CA)	Dysport® (Ipsen, Paris, France)	Xeomin® (Merz, Frankfurt, Germany)
Units/vial	100	500	100
Available doses	50, 100, 200	300, 500	50, 100

Subsequently, Schurch et al. performed a randomized placebo-controlled study of onabotulinumtoxinA in patients with NDO and urinary incontinence. Patients received either 200 or 300 U of intradetrusor onabotulinumtoxinA or placebo (saline) injections. The two treatment groups had significant posttreatment decreases in incontinence episodes, while the placebo group did not. The study was not powered to demonstrate a difference in efficacy between 200 and 300 U doses, but the similarity between the doses lead to further evaluation for the treatment of NDO with the 200 U dose [17].

FDA APPROVAL FOR NEUROGENIC DETRUSOR OVERACTIVITY

Two large, multicenter, double-blind, randomized placebo-controlled trials were subsequently performed with the intent of obtaining an FDA indication for NDO. A total of 691 patients with NDO secondary to multiple sclerosis (MS) (n = 381) or SCI (n = 310) were evaluated. The primary endpoint of the studies was a change from baseline in the mean number of urinary incontinence episodes/week at week 6. Adverse events were recorded. Patients who received 200 and 300 U of onabotulinumtoxinA demonstrated significant improvements over placebo, with a decrease of mean urinary incontinence episodes. Median time to patient request for retreatment was 36.5 and 42.1 vs. 13.1 weeks for onabotulinumtoxinA vs. placebo in the two studies. The need for new onset intermittent catheterization (for patients not on IC at baseline) was approximately 25% higher in the treatment groups as compared to placebo [4,5] (see Table 50.2).

Prior to the introduction of BoNT-A for NDO, female patients who failed medical therapy were offered indwelling catheterization, diapers/pads, or major reconstructive surgery with a bladder augmentation or other urinary diversion [18]. The introduction of BoNT-A in this patient population has provided an alternative, less-invasive treatment option for patients with NDO and medication refractory urinary incontinence. It is likely that in years to come, bladder augmentation will be reserved for patients with refractory detrusor overactivity or impaired compliance that have failed treatment with BoNT-A [19].

A particularly difficult subpopulation of women with NDO are those suffering from MS. Studies show that the prevalence of women to men with MS is >2:1 [20]. This population of patients often experience bothersome NDO coupled with incomplete bladder emptying and, depending on their disease, may lack the manual dexterity to perform self-catheterization. The risk of urinary retention is approximately 25% in patients with NDO given 200 U of onabotulinumtoxinA and 5% in patients with OAB given 100 U of onabotulinumtoxinA (and will be discussed later in the manuscript). Based on these data, we routinely treat women with NDO secondary to MS who are not already on clean intermittent catheterization (CIC) and do not have an elevated postvoid residual (PVR) at baseline with the 100 U dose [4,5,21,22]. Although optimal efficacy may be compromised with the lower dose, the avoidance of urinary retention in many of these patients is crucial as the compromise of upper extremity dexterity seen in many individuals with MS makes intermittent catheterization challenging and could potentially render such patients dependent on indwelling catheterization. This is an area that is presently being studied.

BONT-A AND OAB

As noted previously, BoNT-A was approved for the treatment of refractory UUI in January 2012. OAB is defined as a complex of symptoms comprised of urinary urgency with or without urge incontinence, urinary frequency, and nocturia. Urinary urgency is the sudden onset or desire to pass urine, which is difficult to hold. Frequency is the passage of urine, which is greater than the amount considered to be normal, usually more than 8 voids/day. UTI and other GU pathology must be excluded prior to giving a patient a true OAB diagnosis (ICS, 2005) [23]. Treatment options for OAB include behavioral modification, anticholinergic therapy, Beta-3 agonists, sacral nerve stimulation (SNS), BoNT-A, and posterior tibial nerve stimulation (PTNS). Although it is true that significant progress has made in the treatment options for OAB over the past decade, each option has a risk/benefit profile and providers must help patients select the treatment best for them. Some patients are unable to tolerate side effects from anticholinergic medications (dry mouth, constipation), and some do not experience desired treatment effects. Recent FDA approval of the new Beta-3 agonist for OAB does provide an alternative to anticholinergic medical therapy but does not always provide the desired effects. SNS requires a permanent implant placed in the operating room and PTNS, although with few risks, does require 12 consecutive in office treatments, followed by monthly maintenance visits for continued benefit. BoNT-A can be administered in the office with local anesthesia, although it does require a cystoscopy to administer as well as repeat injections to maintain effects chronically.

OAB EPIDEMIOLOGY AND FINANCIAL IMPLICATIONS

OAB prevalence is estimated to impact 12.9% of women, with nearly half (48%) reporting symptoms of incontinence. Additionally, there is a financial burden associated with OAB [24]. Patients with urinary incontinence have been shown to have higher health-care resource utilization and lower health-related quality of life and productivity [25]. Direct costs of OAB relate to its diagnosis and treatment, and indirect costs include lost time from work and impaired work performance, with additional patient-related factors such as depression, sleep disturbance, skin infection, and UTI [26–28]. A review of the literature by Coyne et al. described a cost analysis incorporating OAB with UUI prevalence rates as well as data on the use of each cost component to calculate annual direct costs in patients older than 25 years. From this, the total cost of OAB in the United States in 2007 was estimated at $65.9 billion, of which indirect costs accounted for 22.1% [29]. The projected cost of OAB in the United States is $76.2 billion in 2015 and $82.6 billion in 2020 [30]. One study has shown that lost productivity costs due to OAB are as high as $841 million dollars/year [31]. With the economic and human burden associated with OAB, one can see how the FDA approval of BoNT-A may prove to be valuable over time.

FDA APPROVAL FOR BONT-A FOR IDIOPATHIC DETRUSOR OVERACTIVITY

Though not an FDA regulatory trial, the first clinical study for idiopathic detrusor overactivity (IDO) and BoNT-A was reported in 2001. Radziszewski et al. treated seven patients with IDO with 300 U of abobotulinumtoxinA and demonstrated that all patients achieved continence after 1 month [32]. Since then, multiple large, placebo-controlled studies have been performed to evaluate the efficacy and safety of BoNT-A for UUI.

Two large, phase III, placebo-controlled studies were conducted involving a total of 1105 patients with OAB and UUI refractory to antimuscarinic therapy. Patients were randomized to receive 100 U onabotulinumtoxinA injections vs. placebo. Patients with idiopathic OAB who experienced three or more urgency UI episodes/3-day period and an average of eight or more voids/day were enrolled. Patients had failed prior treatment with anticholinergic medication due to either lack of efficacy or intolerability of side effects. Notably, urodynamics were not performed in these trials. These studies showed that onabotulinumtoxinA improved continence vs. placebo with a statistically significant decrease in the daily frequency of urinary incontinence episodes vs. placebo. A significant improvement was also seen in a variety of other secondary outcomes such as frequency and urgency as well as quality of life (Table 50.3). Temporary urinary retention requiring the initiation of CIC was more common in the treatment arms of both studies and was approximately 6% greater in the treatment arm. While outcomes were not stratified according to gender, it is likely that these results are applicable to most female patients with urgency urinary incontinence secondary to OAB as the majority of patients in the studies (90% and 88%) were women (see Table 50.3) [21,22].

Prior to onabotulinumtoxinA receiving FDA approval for use in urgency incontinence, Brubaker et al. performed a multicenter trial in women with refractory urge incontinence (defined as having failed at least two anticholinergic medications and at least one supervised behavioral therapy), detrusor overactivity incontinence, and >6 episodes of urge incontinence/3 days. Patients were treated with 200 units of onabotulinumtoxinA or placebo (28 BoNT-A arm, 15 placebo). The primary endpoint was improvement in urge incontinence symptoms 2 months after treatment. A total of 60% of patients treated with onabotulinumtoxinA showed improvements in the Patient Global Impression of Improvement, with a median duration of response 373 days compared with 62 days or less in the placebo group. Because interval analysis revealed 43% of patients receiving onabotulinumtoxinA experienced an elevated PVR requiring initiation of CIC (defined as a PVR >200 cc), the study was placed on hold. It is important to note that the patients were injected with 200 U of onabotulinumtoxinA, double the FDA-approved dose for OAB, and that an elevated residual was arbitrarily defined as 200 cc and did not evaluate whether or not these patients were symptomatic. The study concluded that women with IDO experienced a decrease in urge incontinence episodes with 200 U onabotulinumtoxinA, although with increased PVR and UTI [33].

COMPARISON OF BONT-A TO ANTICHOLINERGIC THERAPY

Comparison of onabotulinumtoxinA with anticholinergic therapy was studied by Visco et al. in a double-blind, placebo-controlled randomized trial in women with idiopathic urge incontinence who had not necessarily failed oral drug therapy [33]. Women with five or more episodes of UUI per 3-day period were randomized to daily oral anticholinergic plus one intradetrusor injection of saline vs. one intradetrusor injection of 100 U onabotulinumtoxinA plus oral daily placebo. The primary outcome was the reduction from baseline in mean episodes of urgency urinary incontinence per day over a 6-month period. The study demonstrated that the women in the onabotulinumtoxinA arm of the study were significantly more likely to report complete resolution of UUI (27% vs. 13%, $p = 0.003$) than those in the anticholinergic group. Both groups had improvement in quality-of-life measurement, without a statistically significant difference between groups. Both oral anticholinergic therapy and onabotulinumtoxinA were associated with similar reductions in the frequency of daily episodes of UUI. The onabotulinumtoxinA group was more likely to have transient urinary retention and UTI, while the antimuscarinic arm reported more dry mouth [34]. While interesting, it is not clear how applicable these data is clinically as onabotulinumtoxinA is presently approved for patients that have failed treatment with anticholinergics, which is not the group studied in this paper.

BONT-A USE IN OAB WITHOUT DO

Although not FDA approved for the indication, BoNT-A may be considered in women with symptoms of urgency/frequency without urodynamic demonstrable DO. BoNT-A use in women with urgency/frequency provides an alternative treatment method for women who have failed medical therapy and desire additional therapy but do not wish to undergo other treatments for refractory OAB including sacral neuromodulation or PTNS. The use of BoNT-A for frequency/urgency without urge incontinence has not been well studied; however, a study by Kanagarajah et al. evaluated 32 patients with OAB with [13] and without [19] incontinence and no evidence of detrusor overactivity on urodynamics. Patients were randomized to receive 100 or 150 U of onabotulinumtoxinA. A statistically significant number of OAB-dry patients had improvement in urinary frequency and OAB-wet patients reported statistically significant improvement in incontinence episodes [35]. According to the AUA/SUFU OAB guidelines, if a patient fails first- and second-line treatments (behavioral therapies and medications), third-line treatments include SNS, PTNS, and BoNT-A injection [36]. It is important to note that of these three treatment options, SNS and PTNS are FDA approved for frequency/urgency (with or without urinary incontinence); onabotulinum toxin is approved for urgency incontinence refractory to antimuscarinics.

BONT-A AND DETRUSOR SPHINCTER DYSSYNERGIA

In addition to its FDA-approved use in patients with NDO, individuals with suprasacral cord lesions, specifically SCI, or MS may suffer from DSD, with the end result of troubling urinary incontinence coupled with incomplete bladder emptying. Although not FDA approved for the indication, several papers describe the off-label use of intraurethral injection of BoNT-A to reduce urethral resistance and improve bladder emptying [37,38]. A prospective study by Schurch et al. evaluated 24 patients with SCI and urodynamically proven DSD, given one of three treatment protocols each receiving at least 25 U of onabotulinumtoxinA using intraurethral or transperineal injections. Ultimately, 50 transurethral and 25 transperineal injections were performed. All but 3 of the 24 patients demonstrated urodynamic improvements after onabotulinumtoxinA injection. Improvements included decreases in maximum urethral pressure during DSD, duration of DSD, and basic urethral sphincter pressure measurement (decreases of 48%, 47%, and 20%, respectively). Of the 24 patients, 9 had a decrease in PVR. The authors noted that this treatment could be considered for patients who are unable to perform CIC or those that do not desire sphincterotomy [39]. Of note, this may be less of an issue with female patients who generally do not have problems with elevated pressures related to DESD and who do not have the options of reflex voiding to a condom catheter. This was demonstrated in the MS population by Lemack et al. who noted that women with MS rarely have issues with upper tract deterioration due to elevated detrusor pressures [40].

BONT-A AND IC/PBS

Although not FDA approved for this indication, the use of BoNT-A in the treatment of IC/PBS has been described. IC/PBS is presently defined as “an unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms of more than 6 weeks duration, in the absence of infection or other identifiable causes” [41]. The pathophysiology of IC/PBS is incompletely understood and is a condition very frustrating to patients suffering from the disease as well as practitioners who often feel treatment options are insufficient. Current treatments are usually unsuccessful at completely alleviating bladder pain and increasing functional bladder capacity [42]. Current management of the condition is directed at palliation of symptoms and relief of pain [43]. A theory behind the mechanism of BoNT-A use in this condition is its decrease in adenosine triphosphate release from urothelial cells. In chemically induced cystitis in rats, injection of BoNT-A into the detrusor muscles increased bladder capacity and compliance [37]. In patients with IC/BPS, inhibition of the neuroplasticity of sensory fibers in the suburothelial space by intravesical BoNT-A injections may target pain and sensory urgency [38]. Based on these principles, several studies have shown that BoNT-A injection in the bladder wall can decrease the intensity of pain in patients with IC/PBS refractory to standard treatments [44–46]. Although a recent review by Mangera et al. concluded that there was a lack of high level of evidence for the use of BoNT-A in IC/PBS, the literature does describe its use [47]. According to the AUA guidelines, BoNT-A use for the treatment of IC/PBS is a fifth-line treatment option, to be used once most other therapies fail [48].

Kuo et al. compared the therapeutic results of onabotulinumtoxinA 100 or 200 U plus hydrodistention vs. hydrodistention alone. A total of 44 patients received suburothelial injection with 200 U (n = 15) or 100 U (n = 29) of onabotulinumtoxinA followed by cystoscopic hydrodistention 2 weeks later. The control group (n = 23) received hydrodistention without onabotulinumtoxinA injection. All three groups had a decrease in symptom score, but pain scale reduction, functional bladder capacity, and cystometric bladder capacity increased only in the two onabotulinumtoxinA groups at 3 months. There was no benefit in using a 200 U vs. 100 U dose of onabotulinumtoxinA in the study in terms of pain relief or increased bladder capacity; however, the higher dose did lead to an increased incidence of urinary retention and difficulty voiding [1,45].

Pinto et al. performed a prospective study to evaluate for the efficacy and safety of repeated intratrigonal injection of onabotulinumtoxinA in patients with IC/PBS by looking at 16 women with symptoms refractory to standard therapy, who received four consecutive injections of 100 U onabotulinumtoxinA 4 months apart. The outcome measures were pain visual analog scale, O’Leary-Sant score, 3-day voiding diary, and quality-of-life questionnaire. The mean decrease in pain score, O’Leary-Sant Score, and urinary frequency and mean increase in voided volume and quality of life were similar after each treatment. Individual symptom relief lasted 6–12 months with average duration of 9.9 ± 2.4 months. Although the study included only a small number of patients, this suggests that there may be some efficacy of onabotulinumtoxinA with repeat injections used for IC/PBS [46].

A literature review by Tirumuru et al. looked at a total of 10 (three randomized controlled trials and seven prospective cohort studies) studies that evaluated a total of 260 patients with IC/BPS treated with onabotulinumtoxinA. Eight of the studies reported improvement in symptoms. Of the 260 patients, 19 required intermittent catheterization at some point after injection. The authors concluded additional studies are needed to clearly determine the benefit for onabotulinumtoxinA use in patients with IC/PBS

[1,49]. In addition, the potential need for regular intermittent catheterization due to temporary incomplete bladder emptying/retention cannot be minimized in this very difficult to treat patient population who often find catheter placement to be very uncomfortable.

Lee et al. evaluated the use of onabotulinumtoxinA in 40 patients, who had failed conventional treatments for ulcer-type (*n* = 10) and nonulcer-type (*n* = 30) IC/BPS. Patients received four sets of 100 U intravesical onabotulinumtoxinA injections every 6 months. After 6 months, 15 patients with nonulcer IC/BPS demonstrated GRA scores ≥2 (previously defined as successful treatment outcome) with the remaining 15 patients with scores <2. All patients in the ulcer group had GRA scores <2, consistent with treatment failure. After injections, all 30 patients with nonulcer-type IC/BPS demonstrated decreased pain scores, frequency episodes, and increased functional bladder capacity, while none of the patients with ulcer-type IC demonstrated any clinical or urodynamic variable improvement. At the conclusion of the study, all 10 patients with ulcer-type IC underwent transurethral cauterization of the ulcers with resultant pain relief. The conclusion of the study was that onabotulinumtoxinA injections might help with pain relief in some patients with nonulcer-type IC, but not in patients with ulcer-type IC [50].

TECHNIQUE OF INJECTION

Different injection techniques have been utilized in the literature, with authors advocating a spectrum of techniques including variables such as depth of injection, volume of diluent, and location template for injection [51,52]. The standard template for most studies including those that led to FDA approval includes a submucosal injection involving the majority of the posterior and lateral walls of the bladder without injection of the trigone (see Figure 50.1).

In most studies, injection of the trigone has been avoided due to the theoretical concern of new onset VUR [11]. A recent randomized controlled trial evaluated the location of injection using abobotulinumtoxinA at 500 U with patients receiving either 20 × 1 mL injections throughout the bladder sparing the trigone or 5 × 1 mL injections in the trigone and 15 × 1 mL injections throughout the bladder. The OAB symptom score was improved up to 26 weeks postprocedure with significant improvements in favor of the group that received injections in the trigone, with neither group developing VUR [51,53].

Another variation in technique of administration is suburothelial vs. intradetrusor injection. A small study evaluated 32 patients with SCI and NDO with all patients receiving 300 U of onabotulinumtoxinA. One group received injections at 2–4 mm depth visualized by ultrasound without suburothelial blebs or bulking seen with injection, while the other group received suburothelial injections, which demonstrated bulking of the urothelium with injection. No significant difference in bladder diary and urodynamic parameters was seen; however, improvement in bladder compliance seemed better in the intradetrusor group [53].

ADVERSE EVENTS

The most commonly seen adverse events associated with BoNT-A injection are incomplete bladder emptying and UTIs. UTI is reported at a rate of between 2%–32% and is usually associated with an elevated PVR [1,54]. Systemic side effects such as generalized weakness have been reported after bladder injection, although this is rare and appears to be related to the dose of the toxin or the formulation used [1,17,55]. A black box warning mandated by the FDA cautions that the effects of the botulinum toxin may spread from the area of injection to other areas of the body, causing symptoms similar to those of botulism. These symptoms include potentially life-threatening swallowing and breathing difficulties and even death. The symptoms that prompted the warning had mostly been reported in children with cerebral palsy being treated with the high doses of the drug for muscle spasticity; however, reports of muscle weakness postinjection for neurogenic bladder has been reported, although with doses higher than the FDA-approved dose of 200 U [55].

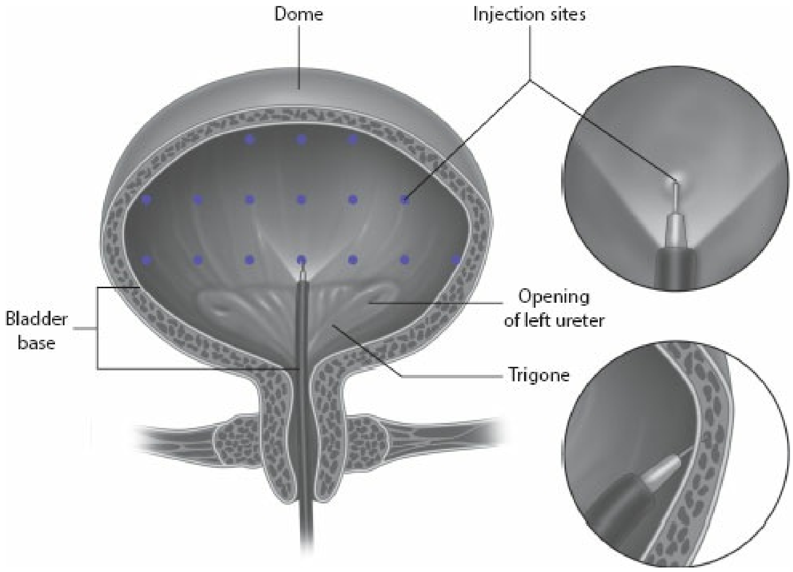

Figure 50.1 OnabotulinumtoxinA injections were administered cystoscopically in detrusor, sparing trigone. (From Ginsberg D et al., *J Urol*, 187(6), 2131, 2012. With permission.)

DOSING

According to the Botox® prescribing information, an individual is not to exceed 360 U of Botox in a 3-month interval for all indications combined. The maximum dose of administration for FDA-approved urological uses is 200 U; however, many patients may be receiving BoNT-A injections for alternative uses (spasticity, cosmetics, etc.). The highest dose studied by the manufacturer in clinical trials is 360 units; thus, that is the highest dose that has been safely studied. Maximum doses are based on the dose at which efficacy plateaus or the dose at which significant adverse events become too frequent [56]. A recent abstract reviewed 13 patients that underwent injection of greater than 360 units for a variety of indications over a 3-month time period and there were no life-threatening adverse events noted [57].

Since BoNT-A is derived from foreign (nonself) proteins, there is a theoretical risk of the development of antibodies from the recipient due to an induced immunological response. The concern with antibody development with BoNT-A is a reduction of therapeutic benefit to the patient. The incidence of neutralizing antibody production (induced antibodies that block the action of BoNT-A) is very uncommon, with rates reported around 4.7% in the original clinical trials predating its use in the urinary tract, which importantly was a BoNT-A formulation known to be significantly more immunogenic than the current clinical formulation. The rates of neutralizing antibody production are now thought to be approximately 1% across various indications [56].

The 12-week interval injection period was based on clinical trial protocols, keeping in mind the avoidance of the potential additive drug effect with minimization of the theoretical potential for antibody generation.

Finally, there is no evidence to support the notion that there is decreased efficacy of BoNT-A with repeated injections. Prior literature has shown continued efficacy with repeat injection of BoNT-A for both NDO and OAB/urgency incontinence [58,59]. In addition, the formulation of anti-Botox antibodies was not identified in any of the phase III trials for NDO or urge incontinence.

CONCLUSION

Since its FDA approval in 2011, BoNT-A has demonstrated therapeutic benefit for patients with NDO and UUI secondary to OAB refractory to alternative treatments. Although not FDA approved for IC/PBS, DSD, or frequency/urgency, certain studies do demonstrate benefit in selected patients. Patients should be counseled regarding the risk of UTI and urinary retention, with volitional voiders receiving treatment aware of the potential need to perform CIC for an elevated PVR. Although some questions remain regarding the optimal injection technique and optimal dose, with time more information likely will become available.

Section VI

Associated Disorders

51 The Overactive Bladder

Marcus J. Drake

INTRODUCTION

Overactive bladder (OAB) syndrome is defined as urinary urgency, usually accompanied by frequency and nocturia, with or without urgency urinary incontinence (UUI), in the absence of urinary tract infection (UTI) or other obvious pathologies [1]. Thus, OAB is a clinical diagnosis derived from a symptom complex centered on urinary urgency and does not require confirmatory urodynamic evaluation. Strictly speaking, "frequency" is simply the number of times someone passes urine in a defined time period; the relevant OAB symptom of passing urine too often by day is "increased daytime frequency (IDF)," and this would been more appropriate phrasing in the definition [2]. An alternative name for OAB is urgency syndrome [1].

The personal and socioeconomic burden of OAB is considerable. OAB is highly prevalent and, while not life threatening, it is associated with a significant adverse effect on quality of life (QoL), sleep quality, and emotional well-being [3,4]. OAB has been proposed to have a greater negative effect on health-related QoL than some other chronic conditions, such as diabetes mellitus, hypertension, asthma, or depression [5,6]. The estimated economic cost attributable to OAB in the United States was estimated at $12 billion per annum in 2003 [7], and this is likely to rise with aging population demographics. The real cost also needs to consider indirect or intangible costs (e.g., loss of earnings, self-purchase of containment products, and reduced productivity). Higher OAB symptom severity is associated with a greater risk of falls [8], especially in the elderly, and this may mean collateral effects, such as fractures, have to be considered in the overall population health burden of OAB. Growing awareness of the scale and impact of OAB has driven recent advances in our understanding of the assessment, pathophysiology, and management of this common and challenging condition.

TERMINOLOGY

Standardized terms to describe OAB and its constituent symptoms were reviewed by the International Urogynecology Association and the International Continence Society (ICS) in 2010 [1]. OAB signifies the presence of lower urinary tract symptoms (LUTS) during the storage phase of the micturition cycle. The constituent symptoms comprise the following:

- *Increased daytime urinary frequency*: Complaint that micturition occurs more frequently during waking hours than previously deemed normal by the woman.
- *Nocturia*: Complaint of interruption of sleep one or more times because of the need to micturate. Each void is preceded and followed by sleep.
- *Urgency*: Complaint of a sudden, compelling desire to pass urine, which is difficult to defer.
- OAB itself remains a symptom complex, and the underlying diagnosis may be related to a number of other conditions, with an overlap with voiding dysfunction in particular.

Detrusor overactivity (DO) is a urodynamic diagnosis [1], indicating the occurrence of involuntary detrusor contractions during filling cystometry. These contractions, which may be spontaneous or provoked, produce a wave form on the cystometrogram, of variable duration and amplitude. The contractions may be phasic or terminal. Symptoms, for example, urgency and/or urgency incontinence, may or may not occur. Neurogenic DO is the term used to describe DO in the presence of a relevant neurological condition. Sometimes, DO and DO incontinence can be triggered by a physical stress such as a cough [9] ("stress-provoked DO"); this should be classified as DO, not misinterpreted as representing stress urinary incontinence (SUI).

Urinary incontinence (the symptom) is the complaint of involuntary loss of urine [1]. It is classified according to the situation(s) reported to cause the urine loss. For OAB, UUI is the complaint of involuntary loss of urine associated with urgency. Mixed urinary incontinence (MUI) is the complaint of involuntary loss of urine associated with urgency and also with effort or physical exertion or on sneezing or coughing. In other words, MUI means the coexistence of UUI and SUI in the same person. A person with OAB not causing incontinence ("OAB dry") who has SUI should not be categorized as having MUI. The relationship between the OAB constituent symptoms and the three types of incontinence mentioned earlier is illustrated in Figure 51.1.

The standardized terms helped to gain coherence in a field that had previously been notable for varied and sometimes conflicting terminology. The term "unstable bladder" was previously generally used to describe both patients with involuntary detrusor contractions during bladder filling on cystometry and also patients presenting with urgency and storage LUTS, who were often treated without urodynamic evaluation. In addition, there were potential misconceptions and negative connotations for patients with the word "unstable." Thus, "overactivity" is the current preferred descriptor.

EPIDEMIOLOGY

In population-based studies, storage urinary symptoms have been reported in 17.4% of women in Europe over the age of 40 [6] and 16.9% women in the United States over the age of 18 [4]. This equates to around 49 million people in Europe and 33 million people in the United States with OAB. Prevalence rises with age, increasing to 31% of women over the age of 75 [6]. Since ongoing expansion of the aged population is foreseeable, OAB will increasingly present a major health-care challenge.

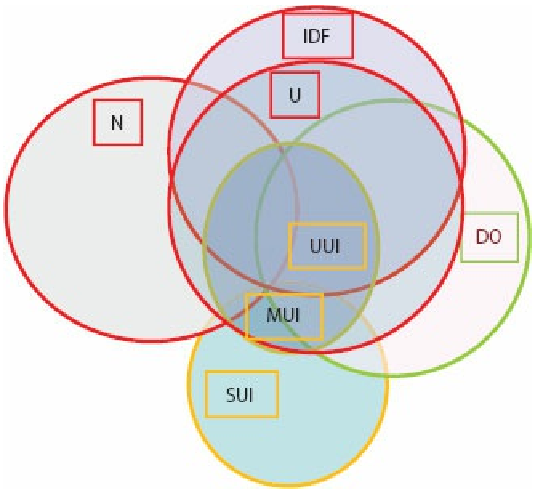

Figure 51.1 The relationship between overactive bladder and incontinence. The symptoms of OAB (outlined in red) are urgency (U), IDF, and nocturia (N). Quite a lot of nocturia is due to nocturnal polyuria unrelated to OAB, so the nocturia ring is shown having a substantial area that does not overlap with the urgency ring. Likewise, the IDF ring does not fully overlap with urgency. There are three major categories of incontinence outlined in orange. UUI is fully within the urgency ring. SUI can occur as an isolated symptom or can be associated with urgency; however, only if SUI occurs with UUI should it be termed MUI. DO (in green) is a urodynamic observation; it usually occurs with urgency, but it can be asymptomatic, and it may be observed in association with SUI.

The EPIC study [10] was a large population-based study quantifying lower urinary tract symptoms according to the current terminology. In 58,139 adults aged 18 or over in Canada, Germany, Italy, Sweden, and the United Kingdom, OAB was reported by 11.8% of the population (12.8% of women and 10.8% of men). Under the age of 60, OAB was more common in women, and over the age of 60, it was more common in men. Of women with OAB, 49.2% were incontinent (OAB wet), compared to 28.7% of men.

Overall, the greatest burden at population level results from urgency, while UUI is the more bothersome for individuals [11]. In a recent systematic review, prevalence ranges of UUI were found to be 1.8%–30.5% for European populations, 1.7%–36.4% for U.S. populations, and 1.5%–15.2% for Asian populations [12]. UUI is associated with depression, UTIs, increased body mass index, and diabetes; furthermore, there is an increased risk of falls in elderly individuals and even deaths [13].

Although OAB symptoms are common, affected people may be reluctant to discuss them. It is estimated that 60% of individuals with storage LUTS seek healthcare, while only 27% receive treatment [6]. Reasons for delay in seeking advice include acceptance of symptoms as being a normal part of aging, particularly in older patients, and the prospect of surgical treatment. Embarrassment and reluctance to discuss the problem with the general practitioner are very common and may be more so in women if the general practitioner is male. One-fifth of women consult a doctor within a year of symptoms becoming troublesome, a third delay for up to 5 years, and a quarter wait for more than 5 years [14]. Consequently, there may be a substantial population of patients with untreated OAB.

PHYSIOLOGY AND PATHOPHYSIOLOGY

The scientific focus in explaining the basis of urgency incontinence symptoms has previously been on DO, which can be evaluated urodynamically and provides an objective and demonstrable abnormality, relevant in both the clinical setting and in animal models. Two main hypotheses have for some time underpinned the understanding of the motor aspects of DO. The first arise from the long-standing recognition of the crucial role of the pontine micturition center (PMC) and the periaqueductal gray (PAG) in controlling the storage function of the bladder and the switching of the lower urinary tract from storage to voiding. The overarching regulatory control intuitively leads one to assume that lower urinary tract problems may derive from alterations in the neural regulatory circuits—the "neurogenic hypothesis" [15]. This neurogenic dysfunction could derive from alterations in the balance of excitation and inhibition or from reorganization of reflexes. Certainly, such changes do appear to be critical in urinary incontinence in many clinical situations. However, it is clear that detrusor muscle itself shows significant changes in its properties in DO—the "myogenic hypothesis" [16]. Receptors on the surface of the smooth muscle are altered in response to various physiological challenges, for example, partial denervation. As a consequence, the muscle can become abnormally excitable, a feature that has been established in animal models of bladder outlet obstruction–induced DO. In addition, the abnormal excitation can spread over an excessive distance, so a substantial proportion of the bladder wall can contract simultaneously, hence giving rise to DO. The increased excitability and abnormal propagation of excitation, perhaps as a consequence of partial denervation, underpins the myogenic hypothesis of DO [16].

In contrast to DO, the emphasis in OAB syndrome is shifted away from the motor side toward the sensations, which patients find most bothersome. Changes in the afferent nerves could in theory give rise to excessive sensory information coming from the lower urinary tract [17]. The afferent nerves within the bladder wall are surprisingly complex and can express a range of transmitters and receptors. Furthermore, nearby cell types could contribute to the generation of sensory information; the urothelium itself and nearby interstitial cells both represent interesting possibilities for modulating the sensitivity of sensory nerve function [18]. Finally, other chemical mediators released within the vicinity of the afferent nerves could alter transmission of sensory activity. Alteration in sensory nerve sensitivity, such that a greater degree of sensory information is transmitted from the bladder than would be expected for a given bladder volume, underpins the "afferent hypothesis" of OAB [17].

The motor and afferent arms converge in the integrative peripheral autonomy hypothesis [19], which focuses on interactions between different cell types in the bladder wall. It describes the presence of localized contractions in the normal bladder and exaggerated localized activity in models of OAB [20] and in humans [21], asserting that such change is a result of increased excitability not only in the muscle but also in the other relevant cell types (interstitial cells and ganglia). Furthermore, excitation can propagate through various cellular channels, including muscle-to-muscle communication (as in the myogenic hypothesis), interstitial cell networks, intramural nerve trunks, or waves of excitation through the urothelium. Widespread propagation of abnormal excitation will give rise to DO, while increased localized distortion will stimulate the sensory nerves and underpin urgency. The relative balance of localized excitability and wider propagation may explain why some people report significant urgency but are not found to have DO on urodynamic testing, while other people have significant urodynamic DO but relatively little in the way of symptoms associated with it.

Modern-day cross-sectional imaging technology is able to give some indication of cerebral and psychological responses to stimuli being conveyed from the lower urinary tract [22]. Functional brain imaging techniques such as functional MRI can look at patterns of brain activation, and definite changes in brain activity have been found in people with LUTS [23,24]. For example, urgency is associated with increased activity in the limbic cortex [25].

Further research is looking at other potential predisposing factors. Wider health issues are recognized, and OAB is associated with obesity, the metabolic syndrome, and insulin resistance [26]. At a genetic level, polymorphism of the ADRB3 gene may be associated with OAB [27], and further advances in this area can be anticipated with the current rapid progress in genetic testing methods.

There is also considerable interest in the role of underlying infections at present (see Chapter 56).

PATIENT ASSESSMENT

Assessment recommended by the International Consultations on Incontinence [28,29] specifies the history and physical examination and minimum investigations, which should include urinalysis (to exclude infection, hematuria, and glucosuria) and a bladder diary. Postvoid residual measurement is particularly indicated when voiding symptoms are present or where impaired bladder emptying is suspected (e.g., coexisting neurological disease).

In addition to characterizing the nature and severity of lower urinary tract symptoms (including associated stress incontinence or voiding symptoms), history should exclude associated visible hematuria or other symptoms suggestive of organic bladder pathology. The differential diagnosis of OAB is extensive (Table 51.1). An account should be taken of the patient's lifestyle including caffeine and alcohol consumption, as alteration of fluid intake may have significant impact on symptoms.

Table 51.1 Differential Diagnosis of Overactive Bladder

- Polyuria due to polydipsia
- Bacterial cystitis
- Bladder cancer
- Bladder stones
- Atrophic vaginitis
- Vaginal prolapse
- Chronic urinary retention
- Interstitial cystitis or painful bladder syndrome
- Nocturnal polyuria
- Drugs (e.g., diuretics)

Symptoms suggesting vaginal wall prolapse, neurological disease, and bowel and sexual dysfunction should be sought specifically, including urinary incontinence related to sexual intercourse. Comorbid conditions should be recorded, in particular a history of diabetes mellitus, congestive cardiac failure, previous pelvic surgery, and neurological disease (e.g., multiple sclerosis or stroke). The possibility of an undiagnosed neurological condition being present should be considered. Coexisting medication may well be relevant, particularly in elderly patients in whom polypharmacy is common (Table 51.2). A cognitive and functional assessment may also be necessary in older women (further details in Chapter 58).

As the adverse effects of OAB relate principally to QoL, an assessment of bother or impact on daily activities has fundamental importance in management decisions. There is a relationship, although not a strong one, between symptom severity and the perception of the degree of bother: 14% of women with mild incontinence have been found to be worried by their storage symptoms, compared with 24% with moderate and 29% with severe incontinence [30]. Sleep interruption due to nocturia and the unpredictable nature of urgency mean that these symptoms impact QoL strongly [5,31].

The most practical and systematic way to capture the crucial information is to use symptom assessment tools (questionnaires). These enable quantification of what symptoms are present, how severe they are, how bothersome, and QoL impact. Several validated condition-specific tools have been developed and continue to emerge, and they serve important roles in research and outcome assessment. Some of the most widely used are from the International Consultation on Incontinence Questionnaires (ICIQ [32]). The total urgency and frequency score (TUFS) is a research tool that weights each void according to its subjective severity on the Patient Perception of Intensity of Urgency Scale and has been validated in patients with OAB [33].

Table 51.2 Drugs Potentially Affecting Continence

- Anticholinergics
- Diuretics
- Alpha- and beta-adrenergic agonists and antagonists
- Calcium channel antagonists
- Antiparkinsonian
- Antidepressants
- Antipsychotics
- Opiates
- Sedatives

Bladder Diary

An invaluable adjunct to patient history, this allows more accurate quantification of daytime urinary frequency and nocturia, functional bladder capacity, nocturnal urine output, and overall urine output. The most simple is the frequency–volume chart (FVC), in which the patient records volume and time of each void and hours of sleep. A minimum of 3 days is suitable for routine assessment [34] and will typically show frequent small volume voids throughout the day and night in patients with OAB. A validated diary has been developed by the ICIQ [35]. Additional parameters can be captured as deemed necessary for the specific circumstances. More detailed charts include incontinence or urgency episodes, and pad usage, though increasing complexity of information captured, or longer duration, is known to reduce patient compliance. Exclusion of nocturnal polyuria (>33% daily urine output voided overnight in patients over the age of 65, or >20% in patients under the age of 65 [36]) is only possible by using FVCs, which are therefore an essential component in the evaluation of nocturia.

Urodynamics

As OAB is a symptomatic diagnosis, the role of urodynamic studies in diagnosis is limited. The majority of uncomplicated patients can begin the management on the basis of clinical assessment alone. In general, cystometry is reserved for those patients who continue to have symptoms despite effective conservative therapy. It provides a means to establish mechanism (such as DO, increased bladder sensations, or inappropriate urethral relaxation), identify any additional relevant mechanisms (such as urodynamic stress incontinence), and look for risk factors that may cause problems with treatment selection (such as impaired voiding). Urodynamic assessment is an interactive test aiming to reproduce symptoms and provide an explanation for them to guide patient management (Figure 51.2). Urodynamic evaluation is appropriate in more complex cases or where invasive treatment is being contemplated. These patients might include those failing to respond to pharmacotherapy and those with suspected bladder outlet obstruction or incomplete bladder emptying, coexisting vaginal prolapse, neurological disease, or previous lower urinary tract surgery. Women with impaired voiding tend to be older, and there is a greater prevalence of diabetes mellitus [37].

Overreliance on urodynamic traces, without referring back to the patient's history or reproduction of symptoms during the test, reduces diagnostic sensitivity of the test and risk of erroneous diagnosis. Failure of cystometry to demonstrate a substantial detrusor pressure rise during an episode of DO incontinence should be interpreted carefully; if the urethral resistance is impaired, then the change in detrusor pressure may be small. Although the symptom of urgency incontinence is suggestive and predictive of the urodynamic observation of DO, a substantial proportion of patients with OAB turn out not to have DO confirmed on UDA. When correlating symptoms and urodynamic results in over 1000 patients, DO was only demonstrated in 44% of women complaining of urgency [38]. Conversely asymptomatic detrusor contractions are frequently seen during filling cystometry in patients without urgency, particularly on ambulatory studies [39].

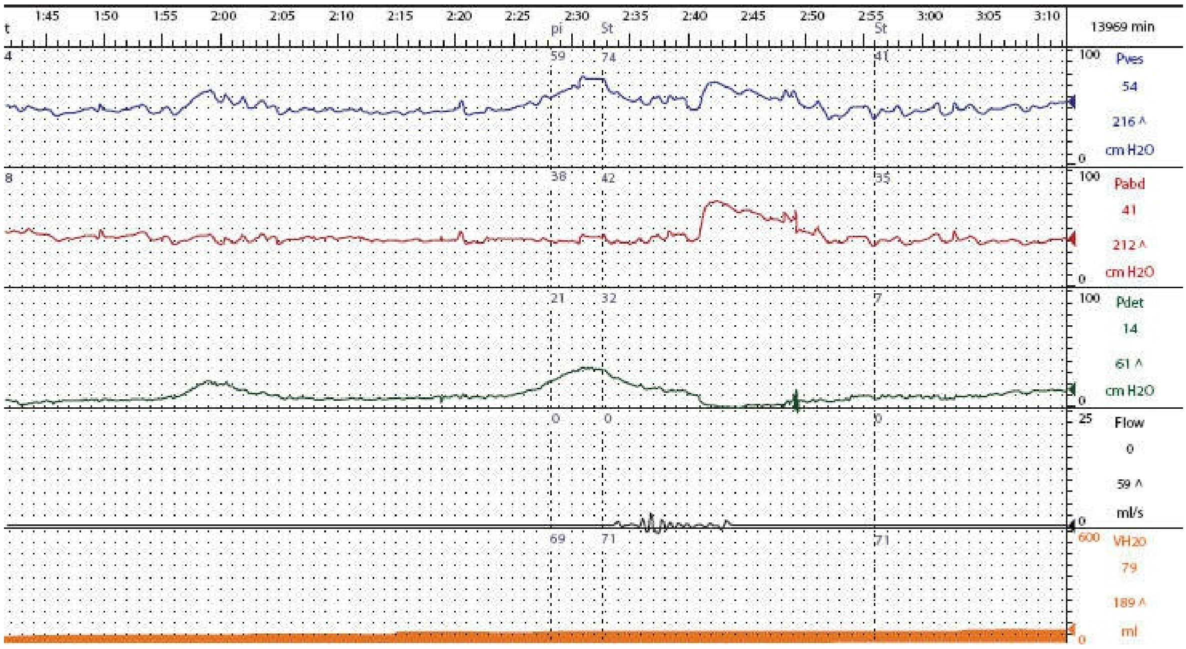

Figure 51.2 Urodynamic trace showing detrusor overactivity incontinence during filling cystometry. The blue trace shows pressure measured in the bladder, and the red line shows that in the rectum (abdominal pressure). The green line represents the difference between the two ("detrusor pressure"), calculated by subtracting red from green. At 2 minutes, the detrusor pressure goes up, signifying DO. At 2 minutes and 30 seconds, it happens again, and this time there is urine flow, i.e., DO incontinence. At 2 minutes and 40 seconds, both bladder and abdominal pressure increase slightly, as the patient contracts her pelvic floor to resist the DO.

TREATMENT

Best results in treatment require good interaction and support from the health-care professional. Explanation is important for compliance and motivation. The Self-Assessment Goal Achievement (SAGA) questionnaire is a patient-completed instrument designed to assess goal attainment in behavioral or pharmacological treatment [40].

Lifestyle Changes

All women with OAB should be managed conservatively in the first instance, and a multidisciplinary approach is important [41]. Many patients benefit greatly from simple advice regarding fluid balance and to minimize tea, coffee, and alcohol intake. Fluid intake can be estimated from the FVC; fluid restriction, including restriction of water-containing foods, may have significant symptomatic benefit [42]. Where caffeine intake is high, a staged reduction in intake may be better tolerated and more realistic for the patient. Significant continence benefits can sometimes be achieved by quite limited weight loss in obese patients, though benefit may relatively greater for those with SUI [43].

Behavioral Therapy

Bladder retraining is considered a first-line therapy in OAB, whether or not patients are incontinent. Bladder retraining involves consistent incremental voiding regimes, aiming to restore central control. Different schedules for bladder retraining include prompted voiding, timed voiding, habit retraining, and bladder drill. Bladder drill has been described using an intensive and regimented protocol performed during an inpatient stay of up to 10 days [44]. Although effective, this may not be compatible with modern health-care systems, and most patients are managed on an outpatient basis with incremental increases in their voiding interval. Focus support groups may be a suitable means to improve compliance. Bladder retraining is often used in combination with antimuscarinic pharmacotherapy [45].

Pelvic floor muscle training may be used successfully by patients with OAB to suppress urgency and UUI episodes [46]. The effectiveness of bladder retraining in combination with pelvic floor muscle training in comparison to either bladder or pelvic floor training alone is as yet unclear, and further investigation is warranted.

Psychological support using various techniques such as cognitive–behavioral therapy may also be helpful. Much of CBT focuses on understanding patterns of behavior and therefore avoiding triggers or conversely trying to accentuate the positives and reduce the influence of negative behavior (Ref CBT for dummies).

PHARMACOTHERAPY

Antimuscarinic Agents

Most women with troublesome OAB will consider drug therapy, and antimuscarinic therapy remains the mainstay of conservative treatment, provided non–drug-based treatment has been tried. All currently available agents are associated with anticholinergic side effects, limiting long-term compliance, such as dry mouth, constipation, blurred vision, and cognitive effects [47,48]. In addition, a significant minority of patients fails to respond adequately. For some of the drugs available, clinical use is based on open studies rather than randomized controlled trials, and the placebo effect in trials of OAB is known to be large [47]. The clinical efficacy and safety of antimuscarinic agents has been reviewed in meta-analyses [47,48]. As the profiles of the agents differ, pharmacotherapy should be individually tailored to each patient according to efficacy, tolerability, comorbidity, and patient lifestyle. Most recently, a paper has shown that the bowel effects of anticholinergics may actually be beneficial [49].

Several antimuscarinic agents are available, with extended-release (ER) formulations and alternative delivery routes, and enhanced bladder or M3 receptor selectivity. Once-daily dosing is considered to improve acceptability to patients. ER formulations have a smoother pharmacokinetic profile and appear to have benefits over immediate-release (IR) formulations in terms of efficacy and tolerability [47]. Other than increasing cystometric capacity, studies with antimuscarinic agents have failed to demonstrate consistent urodynamic effects, yet clear benefit has been demonstrated in terms of frequency, urgency, and incontinence episodes [47]. The International Consultations on Incontinence have produced an expert consensus on available drugs based upon level of evidence and grade of recommendation [29]. Table 51.3 shows currently used antimuscarinic agents receiving high-grade recommendation, based upon good quality evidence. Validated health-related QoL benefits have been demonstrated for several antimuscarinic medications [48].

It is necessary to work with the patient to optimize therapy, including selection of dose and review of dose at follow-up. Dose escalation may be dependent on the extent to which urgency changes at treatment initiation [50]. Adverse effects include dry mouth, constipation, and other effects resulting from the presence of muscarinic receptors in several organs. These effects, and uncertain long-term efficacy, means many patients discontinue treatment. Analysis of the Norwegian prescription database showed that persistence with the initial prescription for new users of antimuscarinic drugs was 38%; 10% switched from the initially prescribed drug to another in the same class, and 52% discontinued altogether [51]. Older people were more likely to persist with the initial prescription, but use of antimuscarinics in older people does carry some risk of cognitive dysfunction [52]. Another situation where caution is needed for antimuscarinic prescription is poorly controlled closed-angle glaucoma.

Table 51.3 Antimuscarinic Agents Recommended for Use in Overactive Bladder

Name	Preparation and dose	Comments
Darifenacin	7.5–15 mg	Highest M3 receptor selectivity (in vitro) Dose escalation possible Once-daily dosing
Fesoterodine	4–8 mg	Active metabolite 5-hydroxymethyltolterodine (5-HMT) Dose escalation possible Once-daily dosing
Oxybutynin	IR 2.5 mg bd–5 mg qds	Most commonly prescribed agent worldwide IR relatively cheap but limited by side effects
	ER 5–20 mg od	ER once-daily dosing
	Transdermal 36 mg twice	Dose escalation possible

	weekly	
		Transdermal avoids metabolite *N*-desethyloxybutynin (reducing side effects) but causes pruritus in 15%.
Propiverine	IR 15 mg od–qds ER 30 mg od	Mixed antimuscarinic (no muscarinic receptor selectivity) and calcium antagonist action
		Most commonly prescribed agent in Germany, Austria, and Japan
Solifenacin	5–10 mg od	M3 receptor selectivity (in vitro)
		Dose escalation possible
		Once-daily dosing
Tolterodine	IR 1–2 mg bd	Bladder selectivity (over salivary gland)
	ER 4 mg od	ER once-daily dosing
Trospium	20 mg bd	Quaternary amine with low lipophilicity, limited CNS side effects
		Low risk of drug interactions
		No muscarinic receptor selectivity

Abbreviations:IR, immediate release; ER, extended release; od, once daily; bd, twice daily; qds, four times daily.

Beta-3 Adrenergic Agonist

The mechanism of action of mirabegron is through binding of beta-3 adrenergic receptors, which cause detrusor muscle relaxation and which are not widespread on other organs. Mirabegron achieves significant reduction in UUI episodes and voiding frequency [54,55], and benefits can be achieved in patients with symptoms refractory to antimuscarinic drugs [56]. The drug is generally well tolerated, and it does not elicit the common side effects seen with antimuscarinic drugs. In the elderly population, symptomatic improvement can be achieved [57], and the concerns regarding potential cognitive impact for antimuscarinics do not apply.

Desmopressin

Desmopressin, a vasopressin analogue, has an established role in treating pediatric nocturnal enuresis and has also been approved for nocturia in multiple sclerosis and nocturnal polyuria [58]. It may be used off-license to treat nocturia in patients with OAB (bedtime administration). Separately, desmopressin given on demand may allow patients to control daytime OAB symptoms [59], including incontinence [60] (daytime or on-demand administration, which should not be combined with nighttime use). Although generally well tolerated, dose titration may be needed, with checks of sodium levels a few days after initiation or dose adjustment. Hyponatremia is recognized in a minority of patients; this is particularly the case in older women and where baseline sodium is reduced [61,62].

Estrogen

Estrogen has an important physiological effect in the lower urinary tract, and estrogen deficiency has been implicated in the pathogenesis of several conditions, including OAB [63]. Although there is currently no evidence to support the use of estrogen replacement in the management of urinary incontinence [53], some benefit has been claimed for relieving symptoms of OAB. Topical administration may be most appropriate [63]. However, the evidence base is not extensive, and the role of this sort of intervention remains limited [64].

BOTULINUM TOXIN A

Botulinum toxin A (BT-A), a neurotoxin produced by *Clostridium botulinum*, is able to cleave proteins within nerve terminals preventing acetylcholine release at the presynaptic membrane. This effect has been harnessed successfully in the management of refractory DO. BT-A is known to counteract release of acetylcholine from nerve terminals, which effectively prevents nerve-mediated muscle contraction. However, clinical efficacy for LUTS treatment is seen at doses that often maintain bladder contraction, so additional effects of BT-A are probably present at the comparatively low doses used for treating idiopathic DO, for example, release of other neurotransmitters or transmitter release from urothelium

[65,66].

Multiple injections are given into the detrusor muscle throughout the bladder under cystoscopic guidance, generally avoiding the trigone. Phase 3 level 1 evidence underpins the licensing using 100 units of onabotulinumtoxinA in idiopathic DO [67]. Numerous other studies have been published (e.g., References 53,68–70) demonstrating benefit in both clinical and urodynamic outcomes. OnabotulinumtoxinA significantly decreases the number of urinary incontinence episodes per day, the number of micturitions per day, maximum cystometric capacity, and volume voided [71]. There is an increased risk of UTIs and raised postvoid residuals. Urinary retention is the commonest complication of BT-A, and although complete acute retention is uncommon, up to a third of patients with idiopathic DO may need to self-catheterize [72,73]. The development of new nerve terminals and neuromuscular contacts allows recovery of function, so the effect is temporary, in terms of both clinical response and need for self-catheterizing. Repeated injections are required in most patients, and although the duration of response varies between studies, efficacy appears to be maintained for several months [74].

NEUROMODULATION AND NERVE STIMULATION

Stimulation of the S3 nerve root (sacral nerve stimulation [SNS]) by an implanted electrical pulse generator can provide effective relief from DO [75]. A period of temporary percutaneous nerve root stimulation is performed to assess clinical response prior to insertion of a permanent stimulator. The stimulator is a small electrical pulse generator, approximately the same size as a cardiac pacemaker, and is usually implanted in the upper outer quadrant of the buttock. Around 80% of patients with a positive test stimulation experience >50% reduction in incontinence at 6 months [76] though this efficacy may not be maintained in the long term [77]. SNS improves number of incontinent episodes per day and pad usage, and surgical revision rates ranged from 3% to 16%, with some patients having the device removed due to lack of efficacy or infection [78]. Complications most commonly reported are implant site or lead site pain (25%), lead migration (16%), bowel dysfunction (6%), and the need for explantation (9%) [76]. Patients need expert assessment and support, adding to the costs of treatment. Although not suitable for routine management, therefore, sacral neuromodulation appears to be effective and safe for a well-selected minority with refractory DO, and its role may increase in the future as the technological development of generators and implant leads progresses.

Intermittent percutaneous tibial nerve stimulation above the medial malleolus has been described for the management of OAB [79]. The technique shows promise in small uncontrolled studies of patients with refractory DO [79–81], and it can be considered as a primary treatment for OAB. It appears that treatment must be continued for clinical efficacy to be maintained [82]. Response rates quoted in studies vary substantially [83]. There are few adverse effects, but the method is a logistical commitment for the patient and for health-care provision.

SURGERY

Augmentation Cystoplasty

Enterocystoplasty aims to create a low pressure reservoir by increasing bladder capacity and reducing filling pressure [84]. The most commonly used technique is the clam ileocystoplasty [85] in which the bladder is split in a coronal or sagittal plane and a patch of detubularized ileum is sutured into the defect. It is indicated in patients with severe refractory DO with a low functional bladder capacity or in patients with high bladder filling pressures endangering the upper tracts (usually in the presence of neurological disease). Good or moderate long-term outcome has been reported in 92% of patients with neurogenic DO but only 58% of those with idiopathic DO [86]. It is a rare procedure in current practice, particularly since the widespread introduction of botulinum toxin, but it does have a role to play in a small number of highly selected cases [87]. Preoperative consideration should be given to coexisting urethral dysfunction in case additional procedures against stress incontinence may be needed.

Postoperative complications include a significant risk of postoperative difficulty with bladder emptying, secondary to a failure to generate adequate voiding pressures. In the long term, most patients need to self-catheterize to empty their augmented bladder adequately [86]. Creation of a continent catheterizable stoma (using the Mitrofanoff principle) is an option in patients unable or unwilling to catheterize via the urethra. Bowel complications are common [88]. Mucus production by the ileal segment may cause problems, and there is a significant risk of urinary infections and stones. Electrolyte and acid–base balance may become disturbed, resulting in a metabolic acidosis, though this is usually subclinical in adults. Rupture of the augmented bladder is a life-threatening complication that may occur in up to 10% of patients [89]. Malignant change rarely occurs within the ileal segment; many of the reported cases have followed chronic cystitis due to conditions such as tuberculosis [90]. Minimally invasive (laparoscopic and robotic) bladder augmentation has been described in small numbers of patients [91,92]. These initial results and any potential benefits over open surgery need further confirmation before a clear role for the techniques can be established.

Autoaugmentation

Detrusor myectomy was developed in an attempt to reduce the risks associated with augmentation cystoplasty [93]. This procedure involves excising the detrusor muscle over the dome of the bladder, leaving the bladder epithelium intact, thereby creating a pseudodiverticulum and increasing bladder capacity. Around 80% of patients with IDO have successful outcome in the medium term, but nearly half have to self-catheterize [94]. Bladder capacity is increased to a lesser degree compared to augmentation cystoplasty but with the advantage of avoiding bowel complications.

Urinary Diversion

Selected patients with disabling intractable incontinence may be best served by urinary diversion, most commonly via an ileal conduit. This may be appropriate if the bladder becomes severely contracted due to severe long-term DO. In this situation, the management of a urinary stoma may be more acceptable to the patient than constantly changing incontinence pads and washing wet underwear. In addition to the risk of stoma complications, it is now recognized that there is a significant long-term risk to upper tract function following ileal conduit formation, due to renal scarring, infection, and stones [95]; these risks must be weighed up against the potential benefits, particularly in younger patients.

CONCLUSION

OAB is a common disorder affecting the QoL of millions of women worldwide; unfortunately, it is often easier to diagnose than to treat. Management remains unsatisfactory in many patients as behavioral modification is often overlooked and drug therapy with anticholinergic medication may be associated with side effects and poor long-term compliance. Two major recent developments are the introduction of mirabegron and the licensing of onabotulinumtoxinA for idiopathic DO. Surgical intervention is associated with significant morbidity and is only appropriate for a minority of patients refractory to, or intolerant of, conservative therapies. Increasing general awareness and decreased tolerance of urinary incontinence has helped to raise the profile of OAB, and pathophysiological advances have helped develop new therapeutic pathways.

52 Neurological Disorders

Ricardo R. Gonzalez, Edward J. Sanchez, David Goldfarb, Renuka Tyagi, and Alexis E. Te

INTRODUCTION

Neural control of voiding involves complex interactions between the central and peripheral nervous systems, the bladder, and the urethral sphincter. Neurological disorders can affect this system in multiple levels, resulting in a disruption in the bladder's ability to store or empty urine. This chapter will systematically review the characteristic voiding dysfunctions as they relate to various disease states.

VOIDING FUNCTION AND DYSFUNCTION

The bladder's ability to store and empty urine is under neurological control. Therefore, any neurological abnormality can result in voiding dysfunction. In general, neurological lesions either cause loss of function (i.e., detrusor underactivity [DU] or denervation) or result in unopposed reflex "overactivity," i.e., detrusor overactivity (DO). DO can be classified as neurogenic detrusor overactivity (NDO) when a relevant neurological condition is present or idiopathic detrusor activity (IDO) if a cause is not known [1,2]. Neurological lesions that cause underactivity usually result in failure to empty, while those that cause overactivity affect the ability to store urine. Neurological lesions can also affect urethral sphincter function, resulting in loss of the usual coordination between the detrusor and striated sphincter, a condition termed detrusor–sphincter dyssynergia (DSD).

To some extent, the anatomic level of neurological injury can predict the type of dysfunction. The three gross anatomic distinctions that predict effect on voiding function are cerebral (suprapontine), spinal (suprasacral), or peripheral (infrasacral). These levels will serve as a structure by which to examine different neurological disorders and their voiding effects later in this chapter. Table 52.1 summarizes characteristic dysfunctions that result from known levels of injury as adapted from Wein [3].

Voiding dysfunction includes failure to store and/or empty urine and can be categorized by the three broad urodynamic categories listed later. Cerebral lesions above the pons usually result in DO with intact sphincter coordination. Suprasacral spinal (i.e., upper motor neuron) lesions result in DO with a variable effect on sphincter coordination. Injuries involving the sacral cord or cauda equina result in lower motor lesions and DU, with or without sphincter denervation [1]. However, neurological lesions can be multiple or incomplete in nature, resulting in a mixed pattern of voiding dysfunction not predicted by anatomic location [4–6].

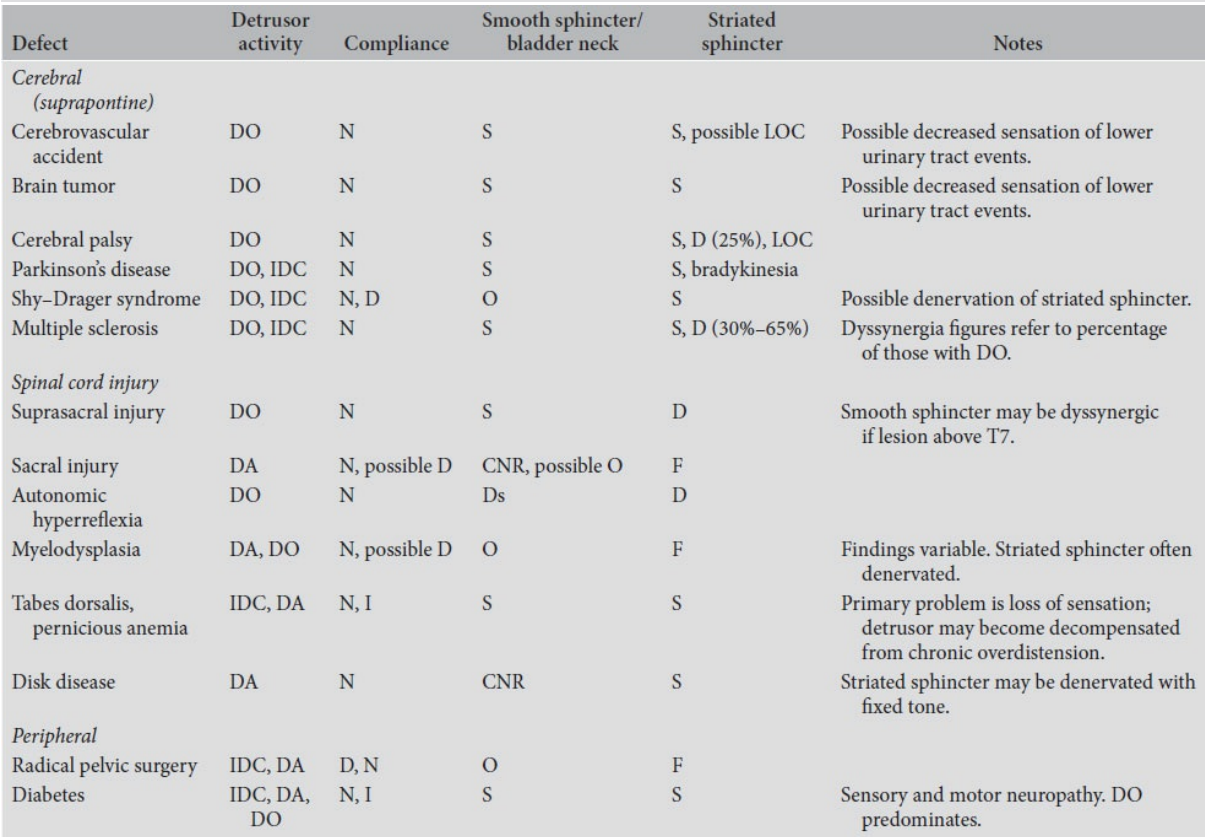
Basic Neurological Control of Micturition

The neural pathways controlling bladder storage and emptying are complex and will only be briefly described in this section. The coordination of bladder emptying involves signaling from parasympathetic, sympathetic, and somatic pathways. The major excitatory signals are from the parasympathetic outflow, originating within the S2–S4 sacral cord segments. Acetylcholine released by postganglionic fibers activates M2 and M3 receptors expressed on the detrusor, to promote activity. Of note, M3 receptors are thought to be the main receptors involved [7]. In addition, parasympathetic nerves release nitric oxide (NO), which inhibits urethral smooth muscle and promotes relaxation [8]. Sympathetic signals arising from the T12 to L2 spinal segments ultimately contribute to the hypogastric and pelvic nerves. Norepinephrine is released from postganglionic fibers and inhibits detrusor activity via β-adrenergic receptors. This same neurotransmitter has excitatory effects on bladder neck and urethra, promoting continence [9]. Finally, somatic motor nerves originating from an area within the lateral ventral horn, known as "Onuf's nucleus," within the S2–S4 sacral spinal cord [10] pass through the pudendal nerve and innervate the striated external sphincter, promoting contraction via cholinergic receptors [9].

The bladder's sensation of fullness is a function of several afferent pathways. Sensory signals from the bladder are sent to the spinal cord via the pelvic and hypogastric nerves, while the bladder neck and urethra send their signals via the pudendal and hypogastric nerves. Two types of fibers within the afferent axons, Aδ (thinly myelinated) and C (unmyelinated) fibers, are involved. Aδ fibers respond to physiological tension, while C fibers remain mostly silent and respond mainly to noxious stimuli. It is important to note that C fibers are widely present in the detrusor and suburothelium and are thought to play a role in urgency and OAB [11].

As the bladder fills, Aδ fibers send signals to lumbosacral spinal tracts and stimulate firing within the sympathetic and somatic efferents to the detrusor and bladder neck, promoting storage. This is known as the "guarding reflex." Signals are also sent to higher centers via pelvic afferents within the spinobulbospinal pathway, reaching the periaqueductal gray (PAG). The PAG sends signals to the pontine micturition center (PMC) and is thought to influence its efferent activity [12]. Within the higher centers, the signal to void or not void is thought to arise from within the medial prefrontal cortex (MPFC) and hypothalamus. During filling, chronic inhibition of the PAG, and thus the PMC, by the MPFC prevents voiding [13].

Table 52.1 Neuromuscular Dysfunction of the Lower Urinary Tract



Defect	Detrusor activity	Compliance	Smooth sphincter/ bladder neck	Striated sphincter	Notes
Cerebral (suprapontine)					
Cerebrovascular accident	DO	N	S	S, possible LOC	Possible decreased sensation of lower urinary tract events.
Brain tumor	DO	N	S	S	Possible decreased sensation of lower urinary tract events.
Cerebral palsy	DO	N	S	S, D (25%), LOC	
Parkinson's disease	DO, IDC	N	S	S, bradykinesia	
Shy–Drager syndrome	DO, IDC	N, D	O	S	Possible denervation of striated sphincter.
Multiple sclerosis	DO, IDC	N	S	S, D (30%–65%)	Dyssynergia figures refer to percentage of those with DO.
Spinal cord injury					
Suprasacral injury	DO	N	S	D	Smooth sphincter may be dyssynergic if lesion above T7.
Sacral injury	DA	N, possible D	CNR, possible O	F	
Autonomic hyperreflexia	DO	N	Ds	D	
Myelodysplasia	DA, DO	N, possible D	O	F	Findings variable. Striated sphincter often denervated.
Tabes dorsalis, pernicious anemia	IDC, DA	N, I	S	S	Primary problem is loss of sensation; detrusor may become decompensated from chronic overdistension.
Disk disease	DA	N	CNR	S	Striated sphincter may be denervated with fixed tone.
Peripheral					
Radical pelvic surgery	IDC, DA	D, N	O	F	
Diabetes	IDC, DA, DO	N, I	S	S	Sensory and motor neuropathy. DO predominates.

Abbreviations:CNR, competent, not relaxing; D, decreased; DA, detrusor areflexia; DO, detrusor overactivity; Ds, dyssynergic; F, fixed tone; I, increased; IDC, impaired detrusor contractility; LOC, loss of (voluntary) control; N, normal; O, open (incompetent at rest); S, synergic.

Several reflexes exist to promote voiding when the sensation of fullness occurs. These are typically held in check until voiding is deemed appropriate. The "bladder–bladder reflex" involves interneurons within the sacral spinal cord, which allow communication between bladder afferent nerves and efferent parasympathetic nerves to the detrusor muscle, promoting bladder emptying. The "bladder–urethral reflex" also involves interneurons between bladder afferent fibers and parasympathetic efferents to the urethral smooth muscle. This promotes smooth muscle relaxation and bladder outlet opening just prior to detrusor contraction [14].

When the decision to void is made, the inhibition by the MPFC is silenced and efferent signals are sent from the PMC to the parasympathetic motor neurons of the detrusor within the spinal cord. Simultaneously, motor neuron activity within Onuf's nucleus is suppressed via inhibitory interneuronal signals. This leads to coordinated contraction of the detrusor along with relaxation of the sphincter, emptying the bladder [15].

Detrusor Overactivity with Synergistic External Sphincteric Function

Incomplete and nontraumatic spinal lesions tend to result in DO with synergistic external sphincter function. Similarly, in patients with lesions above the pons, DO is not typically associated with loss of sphincteric coordination because the lesion is above the level where detrusor contraction is coordinated with reflex urethral relaxation. Typical causes of DO with preserved synergistic sphincteric function include cerebrovascular disease, Parkinson's disease (PD), and some cases of multiple sclerosis (MS) [1,16]. Exaggerated detrusor contractions that occur after suprasacral trauma may be explained by any of the following three mechanisms:

1. Loss of the inhibitory impulse transmission
2. Emergence of primitive alternative micturition pathways
3. Collateral sprouting of new neural pathways [17]

Medical management of DO can usually be achieved with oral or intravesical anticholinergic therapy (see Chapter 41). Newer medications, such as beta-3 receptor agonists, have also been proven effective in the management of DO [18,19]. When DO persists despite medical therapy, intravesical botulinum toxin injection, augmentation cystoplasty, sacral neuromodulation, or percutaneous tibial nerve stimulation (PTNS) may be used to manage DO, resulting in urge incontinence [20–23].

Detrusor Overactivity with Detrusor–Sphincter Dyssynergia

Suprasacral spinal cord injury can disrupt the coordinated voiding reflex between the bladder and external urinary sphincter. This can lead to DO with simultaneous contraction of the striated urethral sphincter [24,25]. This is known as DSD. Typical causes of DSD include suprasacral SCI and MS [26–28]. Identifying DSD is crucial because there is a 50% or greater chance of developing urological complications within 5 years of the onset of DSD [29–31], particularly vesicoureteral reflux and upper tract damage due to the elevation in intravesical pressure (usually when the pressure is chronically above 40 cmH_2O) [32]. Successful management of DO with DSD involves treating both DO and uncoordinated sphincteric contractions. As described earlier, managing DO involves decreasing detrusor activity medically or surgically to allow low-pressure urinary storage. Effective control of intravesical pressure with the anticholinergic therapy can stabilize and even reverse upper tract dilation with DO [33]. Management of DSD includes clean intermittent catheterization (CIC), to bypass the sphincteric obstruction, or by disruption of the urinary sphincter (e.g., pharmacologically with botulinum toxin or mechanically with an intraurethral stent or surgical ablation) [34,35], which may render the patient incontinent. Pharmacological treatments are usually temporary, while mechanical disruption is a more permanent solution. Continuous drainage with an indwelling urethral catheter should be avoided, given the well-characterized complications of infection, urolithiasis, tissue erosion, loss of detrusor compliance, and urothelial cancers. In addition, in those patients with normal sensation, the catheter may be uncomfortable, particularly where there is urethral spasm (DSD). If a long-term catheter is required, then a suprapubic approach is preferable as it reduces the risk of infection and can improve sexual function [36]. It should be noted that DSD is a functional outlet obstruction and therefore cannot be treated safely by condom catheterization or Crede/Valsalva voiding alone.

Detrusor Areflexia (Detrusor Underactivity)

Detrusor areflexia, more recently referred to as detrusor underactivity (DU), is a lower urinary tract dysfunction that may result from a variety of disease processes or injuries. DU was defined by the International Continence Society as a contraction of decreased strength and/or duration resulting in prolonged or incomplete emptying of the bladder (e6). Neurogenic causes of DU include acute CVA, PD, multisystem atrophy, diabetes mellitus, MS, Guillain–Barre syndrome, spinal lumbar disc herniation, infrasacral SCI, and congenital spinal anomalies. DU can also be caused iatrogenically after extensive pelvic surgery [37,38].

In patients with lumbosacral or peripheral nerve lesions, such as myelodysplasia, cauda equina injury, and diabetes mellitus, DU with high or low bladder compliance may develop [1]. Certain upper motor neuron lesions can also result in DU, especially if clinical or subclinical sacral lesions (e.g., coexistent traumatic injury) are present [39]. Examples include acute CVA, cerebellar infarcts, MS, and PD [38]. It has also been noted that hemorrhagic CVAs tend to be more associated with DU when compared to ischemic infarcts [40,41].

Crede/double voiding and/or CIC is the standard treatment for DU [42]. Pharmacological therapies such as alpha blockers may also be used to reduce coexisting urethral outlet resistance. Other available therapies, including muscarinic receptor agonists (bethanechol, carbachol) and acetylcholinesterase inhibitors (distigmine) are used much less commonly due to limited efficacy and unfavorable side effects. Additionally, new therapies such as sacral neuromodulation and stem cell therapy may prove beneficial in the treatment of DU in select patients; however, studies on these modalities remain limited [38]. Because upper tract damage varies directly with increasing time at or above the critical 40 cmH_2O pressure, cases with diminished compliance may also require the use of anticholinergic agents or surgical bladder augmentation to establish urinary storage under acceptable pressure [43].

CONDITIONS OF THE BRAIN AFFECTING THE URINARY TRACT

Cerebrovascular Accident

Cerebrovascular accident (CVA)—stroke—is defined as the acute onset of a focal neurological deficit, usually caused by an occlusive event such as an atherosclerotic thrombus or hemorrhage. Over 800,000 CVAs occur annually in the United States [44]. One-third are fatal, another third necessitate long-term nursing care, and a third allow patients to return home close to their prior level of functioning [45]. The effects of CVA on the function of the lower urinary tract are variable, depending on the location of the neural injury, its size, and etiology [46]. Additionally, because CVAs occur predominantly in the elderly population, evaluation and management are often confounded by coexisting stress incontinence, dementia, and voiding dysfunction from impaired contractility attributable to aging and peripheral neuropathy [45].

Clinical and Urodynamic Features

Clinically, patients may experience a range of voiding complaints from urinary retention, urgency and frequency, and/or incontinence. Neural arcs above the pontine level—where most nonfatal CVAs occur—serve to inhibit micturition. Thus, injury in this area decreases inhibitory control over detrusor function, most often resulting in NDO [47].

While DO is the most common long-term urological problem following a CVA, a significant number of newly affected patients initially develop urinary retention. This retention occurs as a result of "cerebral shock" and may last for a period of several weeks, much like the classic acontractile bladder "spinal shock" phase that immediately follows an SCI [48]. DU is also more commonly seen in cases of hemorrhagic stroke compared to ischemic infarcts [40,41].

Urinary incontinence is common following CVA, with an incidence ranging from 28% to 79%. The etiology of incontinence after CVA is likely multifactorial, with studies linking factors such as depression, impaired cognition, age, dysphagia, hemiparesis, visual field defects, and motor weakness to poststroke incontinence [44]. Limitations in cognitive function and mobility resulting from neural injury may also result in urinary incontinence [49] known as functional incontinence. As recovery ensues, patients most commonly experience urinary urgency. Large studies evaluating the frequencies of the different types of urinary incontinence in the stroke population are limited.

Though most cases of incontinence following CVA are transient, a significant portion of patients will continue to experience incontinence beyond 12 months. Risk factors for persistent incontinence include age, female sex, stroke severity, and prestroke urinary incontinence [44,50].

Although urethral sphincter function is usually preserved, urinary incontinence may result from uninhibited detrusor contractions [51]. Urodynamic testing is useful in differentiating NDO from less commonly seen cases of DU with symptoms of OAB [44,52]. Patients with lesions above the level of the pons characteristically maintain synergetic activity of the sphincter with detrusor contractions [46].

However, patients with suprapontine lesions may purposely increase sphincteric activity during an uninhibited detrusor contraction to avoid urge incontinence. This guarding reflex—termed pseudodyssynergia—may be confused with true dyssynergia by those not familiar with the interpretation of urodynamic studies [53]. As long as urethral sphincter activity remains coordinated with detrusor contraction, intravesical pressure should remain physiological and therefore preserve the function of the urinary tracts.

Evaluation of the stroke patient can be riddled with challenges. Difficulties include obtaining an adequate history, technical difficulty with performing studies, and interpreting urodynamic studies given coexisting findings incidental to aging or comorbidities [45]. However, careful neurological examination and urodynamic evaluation are crucial when assessing the stroke patient who presents for evaluation of voiding dysfunction.

Parkinson's Disease

PD affects men and women equally, primarily in the sixth and seventh decades of life, and it increases in prevalence with advancing age [54]. It occurs with a prevalence of 0.1% in the United States, making it one of the most frequent neurological entities causing voiding dysfunction [55]. Pathologically, the pigmented neurons in the substantia nigra and locus coeruleus in the brainstem degenerate. Systemic clinical features of tremor, bradykinesia, and muscular rigidity are likely due to focal dopamine deficiency in these areas as well as the caudate nucleus, putamen, and globus pallidus [56]. The typical urodynamic findings of patients with PD include DO, sphincter bradykinesia, and impairment of relaxation of the striated muscle component of the urethral sphincter muscle [1,55].

Clinical and Urodynamic Features

Up to 75% of patients with PD experience some degree of voiding dysfunction [57,58]. Nocturia is noted to be one of the most common complaints in patients with PD, reported in >60% of cases [59]. Urgency and frequency were reported in 33%–54% and 16%–36% of patients, respectively [59,60]. Voiding disturbance may also be troublesome, with storage symptoms present in 57%–83% of patients and voiding symptoms reported in 17%–27% [61,62]. Additionally, voiding dysfunction associated with PD in female patients is complex and not always congruent with symptoms [55].

Urodynamic evaluation reveals DO in up to 90% of patients, with sporadic electrical activity of the sphincter during uninhibited detrusor contractions in 61% [16]. In a study of 17 women with PD, stress urinary incontinence was identified in 50% [63]. A unique finding in Parkinson's patients is sphincteric bradykinesia, where there is a delay in relaxation of the external sphincter at the onset of volitional micturition [64]. Additionally, a delayed or incomplete relaxation of the pelvic floor may also be noted [65]. True DSD is a rare finding in PD, seen in <3% of patients [66–68]. Impaired detrusor contractility is also an infrequent urodynamic finding in the patient with Parkinson's [69]. When bladder outlet obstruction due to prostatic enlargement is seen in Parkinson's patients, surgical management may be difficult. In the general population, the risk of incontinence after transurethral prostatectomy is <2%; however, this risk in the Parkinson's patient may be as high as 20% [64].

Care must be taken to differentiate PD from multiple system atrophy (MSA), as the presentation may be similar but urologic management is different. Urinary incontinence, elevated PVR, DSD, urgency, and frequency are all more common in MSA compared to PD [67–70]. In addition, response to surgical treatments is worse in MSA, with incontinence rates after TURP reported as high as 100% [61,71]. Urodynamic evaluation and sphincter electromyography can aid in differentiating MSA from PD. Findings such as an open bladder neck at rest and striated sphincter dysfunction are more commonly seen in MSA than PD [65,72].

More recent attempts to correlate clinical disease states with urodynamic findings have revealed that increasing PD stage results in worsening urge incontinence, DO, and decreasing bladder capacity [73]. Holligar et al. [73] studied 37 idiopathic parkinsonian patients with a mean age of 65 years. Symptoms were classified as mild, moderate, or severe; mild symptoms were unilateral in nature, moderate involved exacerbated bilateral symptoms and deteriorating balance, and severe symptoms required the use of assistance with daily activities and/or ambulation. Table 52.2 summarizes the significant findings. As parkinsonian symptoms worsen, so do clinical and urodynamic parameters. This suggests that bladder function may worsen progressively with advancing disease.

Table 52.2 Clinical and Urodynamic Features of Parkinson's Patients by Severity of Symptoms

Parkinson's severity	Urge	Urge incontinence	Detrusor overactivity	Bladder capacity (mL)
Mild	5/14	0	6/14	380
Moderate	14/14	2	10/14	290
Severe	9/9	4	9/9	260

Neurological evaluation is crucial to evaluate bladder function and to guide appropriate therapy. Urodynamics with simultaneous electromyography is the most sensitive available tool to investigate the nature of voiding dysfunction [55]. The goals of proper management are to improve symptoms and protect the upper urinary tracts. Treatment of the patient with l-dopa can significantly improve symptoms; however, anticholinergic therapy can be added to suppress uninhibited detrusor contractions. Newer pharmacological agents, such as beta-3 receptor agonists, may also be considered. Studies investigating the efficacy of these medications in the Parkinson's patient are needed. Modalities such as deep brain stimulation (DBS) of the subthalamic nucleus have been shown to decrease urinary symptoms, but effects on urodynamic parameters are conflicting [74–76]. Sacral neuromodulation has been shown to significantly improve incontinence, nocturia, and pad usage in patients with neurogenic bladder dysfunction. However, long-term efficacy in patients with progressive neurological diseases, such as PD, has yet to be determined [77].

Cauda Equina Syndrome

Latin for "horse's tail," the term cauda equina is used to describe the caudal end of the spinal cord, known as the conus medullaris, as well as the spinal nerves and nerve roots beginning at the root of the first lumbar nerve. Cauda equina syndrome (CES) is an uncommon, but serious, condition associated with compression of some or all of these nerves, typically by a large, space-occupying lesion located within the lumbosacral canal [1,78,79]. The constellation of symptoms seen may include lower back or groin pain, perineal pain or anesthesia ("saddle anesthesia"), unilateral or bilateral sciatica with varying degrees of lower extremity weakness and/or sensory loss, as well as bladder and bowel dysfunction. Occasionally, a physical exam will also reveal decreased rectal tone [1,3,4]. A high index of suspicion is needed for prompt diagnosis as these changes may progress or become permanent if not treated appropriately with urgent surgical decompression [4,80,81].

Bladder dysfunction, a key element of CES, typically results from an interruption of the complex reflex arcs that control bladder filling and emptying. Both sensory and motor innervations to the bladder are affected. The detrusor muscle is unable to contract appropriately, and patients are often unable to sense that they are full. Additionally, patients may be unable to fully relax their external sphincter, worsening urinary retention and eventually presenting as overflow incontinence [6,82]. Bladder symptoms often resolve if CES is treated in a timely fashion. Prolonged urinary dysfunction has been associated with decompression done beyond 48 hours of diagnosis as well as with the presence of saddle anesthesia, preoperative chronic back pain, and/or rectal dysfunction [5,16,83].

Common causes of CES include lumbar disk herniation, spinal stenosis, tumors, trauma, epidural hematomas/abscesses, as well as iatrogenic causes and postoperative complications such as hematomas after spinal anesthesia or spinal surgery. Interestingly, the use of Gelfoam (Pfizer, New York) in spinal surgeries has also been associated with CES [1].

A detailed history in patients with suspected CES is extremely important and should include questions about changes in bowel/bladder habits. Physical exam should include evaluation of the sacral nerve roots. Palpation of the suprapubic area may reveal a distended bladder, requiring drainage via a Foley catheter. Pin-prick testing of the perineal dermatomes (S2–S4) is important, as patients with CES may often have intact sensation to pressure and light touch. A rectal exam should be done to assess rectal tone and voluntary sphincter contraction. An anal wink test and evaluation of the bulbocavernosus reflex (S1–S3) should also be performed. The reflex involves contraction of the anal sphincter with pressure to the glans/clitoris or traction on the patient's Foley catheter [1,17,84]. If imaging is needed, MRI is the preferred modality [24,85]. This should be done rapidly to avoid delay in treatment.

If one suspects CES in any patient, an immediate neurosurgical consult should be placed. Once CES is diagnosed, urgent decompression should be performed within 48 hours of the diagnosis [1]. Worsened outcomes in sensory, motor, bowel, and bladder function have been demonstrated when surgery is done after 48 hours [5]. Patients should be counseled on the fact that certain genitourinary symptoms may persist, despite decompression within 48 hours, including decreased penile sensation with or without erectile dysfunction in men and decreased sensation and urinary incontinence during intercourse in women [5,25,26,86,87].

Shy–Drager Syndrome (Multiple System Atrophy)

Shy and Drager described a neurological syndrome of autonomic nervous system dysfunction characterized by orthostatic hypotension, anhidrosis, erectile dysfunction, extrapyramidal symptoms, and poor urinary and fecal control [88]. Shy–Drager syndrome is also known as multiple system atrophy (MSA), and it is considered one of the "Parkinson-plus" syndromes of movement disorders [5]. The mean age of onset is 55 years, with a male predominance of 2 or 3:1 [89]. MSA results in the symmetrical degeneration of neurons and associated fibers of motor and extrapyramidal systems, including the cerebellum and brainstem [90]. Disease progression usually results in death 7–20 years after the onset of neurological symptoms [89].

The difference in neuropathological lesion location and number between patients explains the variance in urodynamic findings between Parkinson's patients and those with MSA. Unlike Parkinson's patients, MSA patients tend to have worse lower urinary tract dysfunction, characterized by poor bladder contractility and pelvic floor EMG findings, suggesting that almost 50% demonstrate peripheral denervation [55]. The resulting incontinence is probably caused by DO and some element of paralysis of the external sphincter [91]. Blaivas has demonstrated an open bladder neck during cystography, further indicative of peripheral sympathetic dysfunction [91]. Thus, MSA affects sympathetic, parasympathetic, and somatic nervous systems—compared to the relatively more defined idiopathic PD—and thorough neurological evaluation is invaluable in separating and characterizing these different disease entities [55]. The combination of detrusor dysfunction and sphincter denervation does *not* support the surgical management of symptoms; currently recommended treatment is therefore that of a combination of intermittent catheterization and medical therapy, including anticholinergics and desmopressin [88,92].

Brain Neoplasms

The majority of patients with intracranial neoplasms often maintain control over urinary tract function [1]. Similar to CVAs, alterations in lower urinary tract function will tend to relate directly to the area of the brain affected, rather than the type of neoplasm. For example, compression by tumor or degeneration of neural arcs above the pontine level—such as the superior aspects of the frontal lobe [93] and frontoparietal areas [94] that inhibit detrusor activity—would induce DO with synergetic sphincter function [46,95].

Dementia

Dementia is the loss of thought and reason that results from deterioration and atrophy of both gray and white matter in the brain, particularly of the frontal lobes [1]. Although usually associated with conditions such as head injury, hydrocephalus, encephalitis, syphilis, and Alzheimer's, Pick's, and Creutzfeldt–Jakob diseases, the etiology of neuronal degeneration associated with dementia is poorly understood [56].

The most common urinary symptom is incontinence, with a reported prevalence as high as 90% [96]. However, the cause of incontinence remains unclear; it is not known whether detrusor dysfunction or, more likely, a defect in cognitive function (functional incontinence) is responsible for the lack of social continence in patients with dementia. In one report, 71% of elderly patients with cognitive impairment showed DO; however, 65% of those with no impairment demonstrated DO by the same criteria. Therefore, the incontinence associated with dementia is not likely due to DO [97]. It has been demonstrated that neurogenic incontinence (DO) is more common in multi-infarct and Lewy body disease dementia, while functional incontinence is more prevalent in Alzheimer's disease due to cognitive decline and decreased motivation [98].

Aging, Cognitive Decline, and Conflicting Medication Effects

In both men and women, the prevalence of overactive bladder (OAB) and incontinence increases significantly with advancing age [99]. The impact of OAB can adversely impact quality of life. This includes psychological burden, and an increased risk of falls, fractures, skin infections, and UTIs. In fact, the onset of bladder symptoms is often the deciding factor in transitioning from community to residential-based care. The mainstay of treatment for OAB is antimuscarinic therapy; however, caution is warranted in the elderly population when using these drugs. Anticholinergic side effects include both peripheral nervous system symptoms like dry mouth and constipation and central nervous system symptoms like cognitive impairment, blurry vision, and sleep disturbances. The central nervous system interactions can be the rate-limiting step in treatment if the patient is already beginning to experience cognitive decline. In a population of patients who have had a lifetime to accrue lengthy medication regimens, consideration should also be given to drug–drug interactions. With regard to side effect profiles and pharmacokinetics in the elderly, trospium chloride may be better tolerated than other antimuscarinics including oxybutynin, tolterodine, and solifenacin [100].

The mainstay of treatment for cognitive decline in the aging patient is central cholinergic stimulation [101]. Cholinesterase inhibitors slow the breakdown of synaptic acetylcholine and prolong its ability to stimulate postsynaptic receptors. The three drugs commonly used are rivastigmine, donepezil, and galantamine. While these drugs are designed to target central nervous system cholinergic pathways, associated peripheral nervous system effects include muscle cramps, weakness, cardiorespiratory events, and urinary incontinence. Cholinergic treatment increases OAB symptoms and has even been shown to lead to an incidence of 8% of urge urinary incontinence in those on donepezil [101]. Studies have demonstrated less peripheral cholinergic side effects and less drug–drug interactions in rivastigmine compared to donepezil and galantamine [102].

Clearly, there is a delicate balance when managing OAB and risking cognitive side effects as well as when treating dementia and risking OAB side effects. In cognitively vulnerable populations like the elderly and demented, medical management should consider the use of selective agents with the safest side effect profile and least pharmacokinetic interactions. Newer agents, such as the recently approved beta-3 adrenoreceptor agonist, mirabegron, may be particularly useful in this patient population. Mirabegron was shown to significantly reduce incontinence episodes and micturition frequency, while maintaining a treatment-emergent adverse event profile similar to placebo [18]. Newer studies suggest that combinations of mirabegron and solifenacin may achieve increased efficacy with virtually no change in safety profile compared to solifenacin monotherapy [19].

Multiple Sclerosis

MS is the most common disabling neurological disorder affecting people between 20 and 50 years of age [103]. It is characterized by focal inflammatory and demyelinating lesions of the nervous system, affecting mainly those living in the temperate climates. Prevalence is estimated at 1/1000 in Americans, 2/1000 in Northern Europeans, and 20 to 40/1000 in first-degree relatives of patients with MS [103–105]. In approximately 60% of patients, the disease is initially manifested by exacerbations and remissions. The clinical course of MS can be acute, progressive, chronic, and/or benign [106].

Neurological dysfunction is caused by demyelinating plaques of the white matter of the brain and spinal cord, especially the posterior and lateral columns of the cervical cord, which serve as pathways for neurological control over vesical and urethral function [107]. These plaques are caused by an autoimmune response and attach to the central nervous system myelin, leading to a loss of salutatory conduction and conduction velocity in axonal pathways [103].

Clinical and Urodynamic Features

Voiding dysfunction is experienced by 90% of patients with MS [108]. Interestingly, a change in bladder function is the presenting complaint in at least 10% of MS patients [109]. These include not only frequency, urgency, and urge incontinence but also urinary hesitancy, intermittency, and poor urinary stream. The nature of voiding dysfunction is most dependent on the location of the plaque formation, such as intracranial, suprasacral, or sacral cord plaques.

Urodynamically, the most frequent pattern seen is DO, which is observed in 50%–99% of patients [103,108,110,111]. DSD is also documented in up to 50% of patients with DO [28,112,113]. Of patients with symptoms suggestive of obstruction, 73% had DU [114]. DU is seen in 20%–30% of patients, most of whom usually strain to void [115]. Hypocontractility may be related to cerebellar plaque involvement, lack of cortical facilitatory input, or sacral cord involvement. Some evidence suggests that DU is a temporary condition that may progress to DO in 57%–100% [114]. Although these patients may be managed effectively with an intermittent catheterization program, periodic urodynamic reevaluation is essential to ensure protection of the upper urinary tract [116]. Given the waxing and waning nature of MS, reevaluation is especially important because the neurourological status of the patient with MS may change over time. Having said that, DSD revealed on urodynamic evaluation rarely remits [114].

Optimal management of lower urinary tract dysfunction is based on the avoidance of indwelling catheters and minimizing intravesical storage pressure while assuring low-pressure urinary drainage [116]. Urinary storage pressure is minimized with anticholinergic medications or augmentation cystoplasty if medical therapy is ineffective [117]. Unfortunately, sphincterotomy is not an option for women, and many women with neuropathic bladder dysfunction are treated in the community with indwelling urethral or suprapubic catheters [1]. However, early experience using botulinum toxin injections into the sphincter for the treatment of DSD is limited but growing and may eventually prove to be a therapeutic option [118,119]. A randomized, double-blind, placebo-controlled study investigating botulinum toxin's effect on DSD in MS patients showed that botulinum toxin significantly increased voiding volume and decreased premicturition and maximal detrusor pressures. It failed, however, to decrease postvoid residual volume [120].

CONDITIONS OF THE SPINAL CORD AFFECTING THE URINARY TRACT

The degree of voiding dysfunction associated with spinal cord conditions is related to the process of the condition itself, the area of the spinal cord affected, the severity of neurological impairment, and the coexisting pelvic floor pathology. Neurological injury, which can involve parasympathetic, sympathetic, and somatic nerve fibers, can result in a complex array of signs and symptoms. Urodynamic investigation of those with neurological impairment is essential as it provides objective information regarding the nature and extent of the effect on lower urinary tract function. Such information is invaluable in adequate patient management.

Spinal Cord Injury

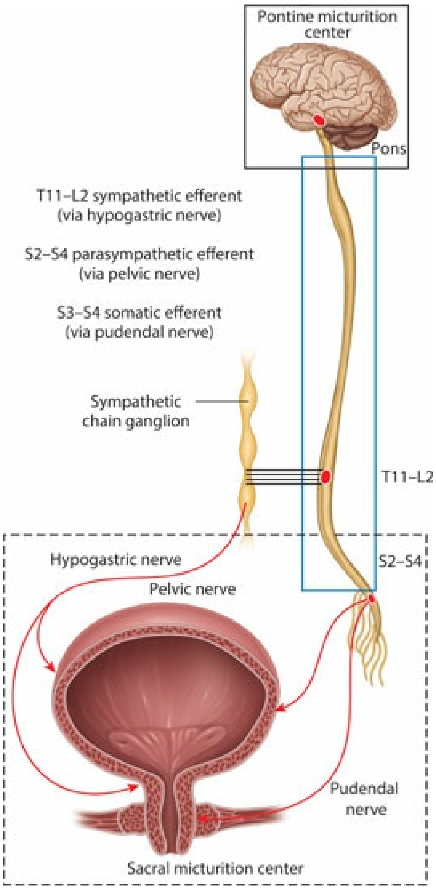
Neurogenic lower urinary tract dysfunction resulting from spinal cord injury (SCI) is an excellent model for understanding neurourological dysfunction. The principles of urological evaluation and management of traumatic SCI patients are applicable to those with other spinal cord pathologies [34]. The estimated annual incidence of SCI reaches 40 new injuries per million population in the United States, or approximately 11,000 new cases per year—with a prevalence of approximately 247,000 persons [121]. With 85% of injuries occurring at or above the T12 level [122], the reported neurological level and the extent of the lesion of SCI at hospital discharge reveal 34.3% of patients with incomplete quadriplegia and 25.1% with complete paraplegia; 22.1% of patients develop complete quadriplegia and 17.5% incomplete paraplegia [121]. Historically, the most common cause of death in SCI patients had been secondary renal failure; however, improved medical assessment and management has led to dramatic shifts in the causes of death [1]. Nonetheless, lower urinary tract dysfunction following SCI is frequent and may result in infection, urolithiasis, upper tract failure, and lower urinary tract symptoms.

Clinical and Urodynamic Features

Characteristics of voiding dysfunction after SCI are dependent on the stage of recovery, i.e., spinal shock, recovery, and stable phases [1].

Immediately following spinal cord trauma, *spinal shock* occurs. This phase characteristically presents with flaccid paralysis and absence of reflex activity below the level of the lesion. Voiding symptoms typically include urinary retention due to DU that may last for months. The DU usually resolves weeks to a few months following the SCI with resumption of reflex detrusor activity. While in acute retention, patients should be managed with a regime of intermittent catheterization.

The *recovery* phase follows spinal shock and is marked by the return of reflex detrusor activity. This phase is noted clinically by the appearance of new incontinence, autonomic dysreflexia (AD), or lower extremity spasticity. The neurological level of the SCI often corresponds to the resulting type of lower urinary tract dysfunction (Figures 52.1 and 52.2). Performing urodynamic testing at this time is key to understand the pathophysiology of each patient's condition [123,124]. With cervical or thoracic spinal cord lesions, the most common outcome will be DO with DSD. Sacral spinal cord injuries are commonly associated with DU, although this may also be seen with higher-level lesions. Injuries of the lumbar spine are more difficult to predict, with lower urinary tract dysfunction ranging from DO with DSD, or DO with sphincter deficiency, to DU.



Pontine micturition center

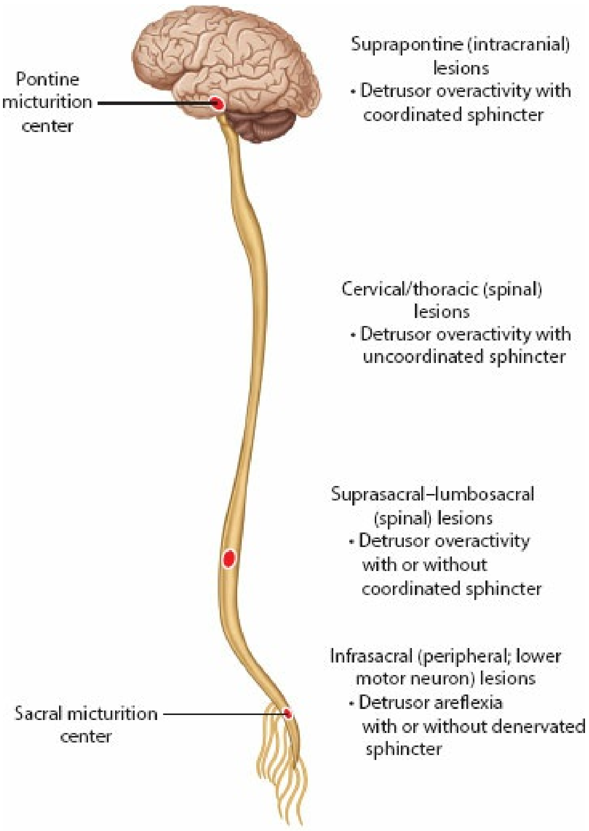
Pudendal nerve
Sacral micturition center

Figure 52.1 Innervation of the lower urinary tract. The control of micturition and continence arise at three levels: suprapontine (thin line box), spinal (thick line box), and peripheral/infrasacral (dashed box). Each level contains distinct nerve fibers with complex interplay between all levels.



Pontine micturition center
Suprapontine (intracranial) lesions
• Detrusor overactivity with coordinated sphincter
Cervical/thoracic (spinal) lesions
• Detrusor overactivity with uncoordinated sphincter
Suprasacral–lumbosacral (spinal) lesions
• Detrusor overactivity with or without coordinated sphincter
Infrasacral (peripheral; lower motor neuron) lesions
• Detrusor areflexia with or without denervated sphincter
Sacral micturition center

Figure 52.2 Urodynamic outcome following complete denervating injury. Outcomes are dependent on level and extent of injury. Incomplete or partial lesions may lead to variation in urodynamic findings.

The final phase following SCI is labeled the *stable* phase and by definition is the period characterized by the absence of additional neurological recovery or change in urodynamic pattern [1]. Although the pattern of voiding pathology remains stable, there can be an increase in the severity of the dysfunction and/or a continued loss of compliance. Therefore, it is critical to continue periodic evaluation of lower urinary tract function and surveillance of the upper urinary tract for further sequelae.

The level of spinal lesion and its relationship to lower urinary tract dysfunction have been documented and evaluated in 489 consecutive patients presenting with SCI [123]. In 104 patients with cervical SCI, 15% (16 patients) had DU. In the remaining 85% (88 patients), involuntary detrusor contractions (IDC) were documented, with 65% (57 of 88) exhibiting concurrent DSD. All 87 thoracic SCI patients were found to have DO, and 90% of them exhibited concurrent DSD. Lumbar SCI was found to have the least predictable urodynamic patterns, with 40% having DU, 30% with DO, and 30% with DO with DSD. In the sacral SCI cohort, 12% of patients had normal urodynamic studies, while 64% of patients had DU.

Urological management of patients with SCI should focus on allowing low-pressure storage and efficient bladder drainage at low detrusor pressures. DU may be managed with CIC. If hand function is poor, other methods of urinary drainage may be utilized, including placement of a suprapubic catheter or urinary diversion. Long-term urethral catheters should be avoided due to the risk of infection, urolithiasis, erosion, and urothelial metaplasia and cancer. DO may be managed with a variety of treatment modalities including anticholinergic medications, beta-3 receptor agonists, and intravesical injections of botulinum toxin. If safe bladder pressures are unable to be achieved with conservative methods, patients may ultimately require augmentation cystoplasty or urinary diversion. In patients experiencing DSD, CIC remains the gold standard. Sphincteric injection of botulinum toxin has also shown promise; however, large, randomized trials are lacking. Other treatments include sphincterotomy and urethral stenting; however, these may be associated with significant complications and increased morbidity. In addition, the usual need for an external collecting device precludes their use in females [125].

Brown–Sequard Syndrome

Hemitransection of the spinal cord results in this rare, but well-documented condition with pathognomonic findings for a spinal cord injury [126,127]. The classic presentation of this syndrome—provided that it results from a single spinal lesion—is ipsilateral hemiparesis (pyramidal tract) of the leg with contralateral loss of superficial sensation (spinothalamic tract) and ipsilateral loss of deep sensation (dorsal tract). The variable presentation that results in either motor or sensory symptoms depends upon the plane of the lesion.

Clinical and Urodynamic Features

Voiding symptoms are variable among these patients. Those presenting with more severe motor deficits (i.e., intramedullary diseases) are more likely to have symptoms ranging from urinary retention to filling phase symptoms such as frequency and urge incontinence [128]. However, there is no relationship between voiding symptoms and the laterality of the lesion or concurrent sensory disturbances [128–130]. There is also a paucity of publications reporting urodynamic studies in these patients with findings that are concordant with voiding symptom severity. The most frequent urodynamic findings in symptomatic patients tend to be DO and areflexia [123,128]. Because the relationship between the spinal lesion and resulting voiding symptoms is variable, thorough neurological examination paired with urodynamic evaluation are key in managing symptoms and protecting the upper tracts of each patient.

Autonomic Dysreflexia

AD is a well-defined syndrome of acute excessive sympathetic output that occurs in patients with spinal cord injuries, most commonly above the T6 level. This condition is associated with an uncontrolled spinal reflex mechanism from afferent visceral (or other noxious) stimulus below the level of the lesion, resulting in, if not managed appropriately, a life-threatening hypertension. The most common cause is stimulation of the lower urinary tract, with 75%–85% of cases precipitated by bladder distension [131]. Other triggers include infection, urethral distension, instrumentation, stones, decubiti, gastrointestinal pathology, long bone fracture, sexual activity, and testicular torsion [125].

At presentation, the symptoms associated with AD generally include a bilateral pounding headache, with diaphoresis above the level of the spinal lesion, nasal congestion, malaise, nausea, and visual blurring. The signs observed commonly are flushed sweaty skin above the level of the lesion with cool, pale skin below that level. The main finding is elevation of the blood pressure with reflex bradycardia—which in a post-SCI patient may mean that readings of 120/80 mmHg are elevated, as base pressures in these patients are often in the 90/60 mmHg range [1]. Less commonly, tachycardia or arrhythmia may also be noted [125]. The labile hypertension associated with the AD response can result in intracranial hemorrhage and death [132]. Early recognition of the syndrome is critical, with initiation of management immediately [133]. If AD does not reverse with bladder decompression, pharmacological management with oral nifedipine, nitroglycerine ointment, or IV nitroprusside should be initiated.

Several studies have reported success with prophylactic use of selective α-adrenergic blockers, such as terazosin, for long-term management [134,135]. Even if prophylaxis is utilized, careful monitoring during procedures remains an absolute necessity. Any endoscopic procedure in susceptible patients should ideally be done under spinal anesthesia or general anesthesia with close monitoring [125].

Intervertebral Disk Disease

Voiding dysfunction is a well-established complication of lumbar intervertebral disk herniation, resulting from displacement of any intervertebral disks into the spinal canal. Herniated disks occur in a variety of disease processes including degenerative disease and trauma. The symptoms resulting from the displacement will be dependent on the level of the lesion, the extent of the displacement, and the type of neural injury, which may involve parasympathetic, sympathetic, and/or somatic nerve fibers (Table 52.3). The combination of these factors will result in a complex combination of signs and symptoms.

Nerve conduction will be compromised in cases of acute compression. At the level of the sacrum, this can result in DU from impaired autonomic outflow to the detrusor. If there is additional interference of somatic outflow at the pudendal nerve, concomitant intrinsic sphincteric deficiency may occur [136].

The most frequent site of lumbar disk herniation is the L4–L5 and L5–S1 intervertebral spaces, which can result in CES [83,137]. The characteristic symptoms and signs in this syndrome include lower back pain, obstructive voiding symptoms with or without incontinence, sensory loss at the perineum, sensory loss of the lateral foot (S1–S2 dermatome), and absence of the bulbocavernosus reflex [138]. Disruption from gradual degenerative disk displacement may result in hyperexcitability of sensory and motor fibers, with symptoms including irritative urinary frequency and urgency with DO [139]. Urodynamic testing should be an integral part of the evaluation of all patients with incomplete lumbosacral spinal injuries [1].

Table 52.3 Innervation of the Lower Urinary Tract

	Spinal cord level	**Function**
Afferent		
Nociceptors	S2–S4	Initiation of micturition
Sensory	S2–S3	Perineal sensation
Efferent (autonomic)		
Sympathetic (hypogastric nerve)	T11–L2	Sphincter contraction, bladder relaxation
Parasympathetic (pelvic nerve)	S2–S4	Bladder contraction
Somatic (pudendal nerve)	S3–S4	External sphincter contraction

Ankylosing Spondylitis

A rare inflammatory disease of the spine, ankylosing spondylitis results in fusion of the joints and ligamentous calcification. This disease predominantly affects men, with deleterious effects on neurological function generally occurring following spinal cord compression, caused by either atlantoaxial subluxation or trauma to the rigid spine [140–142].

The most common neurogenic lower urinary tract dysfunction caused by ankylosing spondylitis results in a CES with impaired detrusor contractility [140]. More severe cases may result in DU, and sphincteric activity may also be compromised as neuropathy progresses. Surgical decompression following neurological impairment has met with varying success [143].

Guillain–Barré Syndrome

Guillain–Barré syndrome is an inflammatory demyelinating polyneuropathy, usually arising following an infectious episode that primarily affects the peripheral nervous system, with some effect on the nerve roots [144–146]. Although recovery is a hallmark of Guillain–Barré syndrome, 85% of patients sustain persistent neurological deficits [147]. In severe cases, progression continues to affect central nervous, respiratory, and autonomic function, often including urinary retention [148].

Lower urinary tract dysfunction is present in 6%–40% of patients diagnosed with Guillain–Barré syndrome [149]. Symptoms include detrusor and sphincter motor and sensory deficits consistent with variation in the combination of nerves affected during the course of Guillain–Barré syndrome [150,151]. Urodynamic studies on patients with Guillain–Barré syndrome have revealed DU, impaired bladder sensation, and occasionally DO; it is not known whether these findings are accounted for by either central nervous system involvement or the timing of the urodynamic study [151,152].

Tabes Dorsalis

Tabes dorsalis (locomotor ataxia) is an uncommon form of neurosyphilis affecting less than 5% of people with syphilis. This condition results in a demyelination of the dorsal columns in the spinal cord [153–155]. Progression of sacral root and dorsal column degeneration results in advancing stages of disease and ultimately is manifested urologically with the development of urinary retention [156].

Classic descriptions of the effects of tabes dorsalis on voiding discuss the prevalence of DU; however, more recent studies suggest that DO may occur [154]. It is postulated that involvement of the conus medullaris or cauda equina predisposes to a poorly compliant areflexic bladder and that suprasacral lesions are responsible for the DO in these cases [157]. These patients can be managed effectively with the treatment of the primary infection with antibiotics and an intermittent catheterization program [158].

Human Immunodeficiency Virus

Voiding dysfunction in patients with human immunodeficiency virus (HIV) of variable etiologies has been documented in recent studies [159–161]. A common cause of lower urinary tract symptoms is urinary tract infection. HIV-infected patients experience a greater number of urinary tract infections compared to the general population and are particularly vulnerable when CD4 counts fall below 500/mm^3. Etiology may include common uropathogens, but one should consider less common causes of infection such as fungi, parasites, mycobacteria, and viruses when disseminated infection occurs [162].

A complete urological assessment is critical in the evaluation of any complaints suggesting voiding dysfunction, especially as up to 40% of patients with AIDS have associated neurological dysfunction [163,164]. Neurological pathologies in AIDS patients, which can lead to voiding dysfunctions, include toxoplasmosis (reported in 14% of AIDS patients with neurological disease [164]), neoplasms of the central nervous system, lymphoma, systemic lymphoma with central nervous system involvement, and Kaposi's sarcoma [165–167].

Urodynamic Evaluation

Findings following urodynamic evaluation in patients with AIDS are variable and may include DU, DO, DO with DSD, or nonneurological bladder outlet obstruction [160,164]. In the study by Hermieu et al., the onset of lower urinary tract disturbance represented a poor prognostic indicator, as 44% of these patients died within 24 months of evaluation [160].

Tropical Spastic Paraparesis

Tropical spastic paraparesis is a condition of progressive paraparesis and back pain, most likely induced by infection with the retrovirus human T-cell lymphotropic virus type 1 (HTLV 1) [168]. This clinical entity is caused by meningomyelitis with demyelinization and axonal loss, which can involve the corticospinal tracts [169]. There is significant voiding dysfunction associated with this syndrome, with urinary hesitancy, urgency, and incontinence found in up to 60% of patients [168].

Urodynamic Evaluation

Studies of affected patients have revealed a predominance of DO, often with impaired contractility at voiding and less frequently DU [170,171]. Despite variable presentations, the lower urinary tract dysfunction can precipitate upper tract deterioration; therefore, urodynamic evaluation is recommended in all patients with acquired immune deficiency syndromes with voiding symptoms [163].

Transverse Myelitis

Transverse myelitis is a rare inflammatory condition of the spinal cord, which may affect children or adults in an acute or progressive fashion [172,173]. The entire thickness of the cord is involved, including both the gray and white matter, with the diagnosis made following elimination of spinal cord compression and the absence of other neurological diseases [174]. Affected individuals may suffer from persistent neurological deficits, most commonly urologic, although complete recovery may occur within 3–18 months [174,175].

Urodynamic Evaluation

Lower urinary tract dysfunction in these patients usually presents as either urinary retention or incontinence. A recent study showed the outcomes with predominant DO, DO with DSD, and less frequently DU [176]. These urodynamic findings often persisted despite complete neurological recovery.

Lyme Disease

Lyme borreliosis is caused by the spirochete *Borrelia burgdorferi*, which has demonstrated the ability to invade numerous body tissues, including the central and peripheral nervous systems and the bladder [1]. Although initially associated with urinary retention, symptoms of urinary urgency, urge incontinence, and nocturia may occur at any time during the disease process [177]. Patients with Lyme disease may present with DU or DO [178]. Although the disease may respond to a 2-week course of antimicrobial therapy [179], those with relapsing and remitting symptoms may require long-term administration of antimicrobials [180].

Herpes Zoster

Reactivation of persistent varicella virus from a dorsal root ganglion will result in episodes of herpes zoster [181]. During such episodes, symptoms primarily include sensory disturbances such as pain and paresthesia, although paralytic complications do rarely occur [182].

Infrequently, the virus reactivation includes the autonomic nerves of the bladder, with resultant irritative voiding symptoms such as dysuria and frequency. In cases involving the afferent neurons of the sacral micturition reflex arc, somatic and visceral motor neuropathy can occur, and urinary retention may ensue [183,184]. The course of the viral infection is usually self-limiting, with spontaneous recovery typically occurring within several months [1,185].

Poliomyelitis

Following a World Health Organization resolution in 1988, great strides have been made in the eradication of poliomyelitis worldwide, with only 11 countries currently affected with endemic polio [186]. Poliomyelitis results in destruction of the gray matter of the anterior horn cells and selective destruction of large-diameter fast-conducting motor neurons [187]. Polio is essentially a pure motor neuropathy with sensory function usually preserved [188]. Urinary retention may occur in up to 40% of patients, depending on disease severity. Patients with post-polio syndrome may manifest an increased incidence of irritative lower urinary tract symptoms, although studies on this issue are incomplete [1].

Urodynamic evaluation reveals DU when testing affected individuals, with bladder sensation and anal sphincter function remaining intact [189].

Tethered Cord Syndrome and Short Filum Terminale

The tethered cord syndrome results from impediment of the cephalad migration of the conus medullaris and may result from a short filum terminale, intraspinal lipoma, or fibrous adhesions resulting from the surgical repair of spinal dysraphism [190,191]. The syndrome is classically diagnosed in children, especially during adolescence, but rarely, the process may occur in adulthood [192,193]. Lower urinary tract dysfunction is common in this syndrome, and, in otherwise asymptomatic children, urodynamic abnormalities may be the basis for surgical intervention [194].

Urodynamic Evaluation

Detrusor areflexia has been reported in 60% of patients, although recovery of lower tract function approached 60% with surgical release of the cord [192]. Similarly, DO has also been reported [195]. In another series, 22% of patients with tethered cords had DO; all improved following spinal surgery [196]. Early and aggressive neurosurgical correction is therefore indicated [197].

CONDITIONS OF THE PERIPHERAL NERVOUS SYSTEM AFFECTING THE URINARY TRACT

Pelvic Plexus Injury

The major sympathetic and parasympathetic innervation of the lower urinary tract follows the branching array of the pelvic plexus. These nerve fibers can be disrupted during complicated pelvic surgical procedures, or following pelvic fracture, with resultant lower urinary tract dysfunction. Sympathetic (thoracolumbar) nerves promote urine storage by relaxing the detrusor muscle and relaxing the bladder outlet. Parasympathetic (sacral) nerves stimulate detrusor contraction. If the primary injury affects the parasympathetic nerve fibers, generally there is impaired detrusor contractility, although DU may occur in severe instances [1]. Similarly, in cases involving predominately sympathetic innervation, the resultant symptoms usually include intrinsic sphincter deficiency with stress urinary incontinence. Study of patients with voiding dysfunction following major pelvic surgery has shown resolution of symptoms in 6 months for up to 80% of affected patients [198].

Abdominoperineal Resection

Abdominoperineal resection (APR) for rectal cancer almost invariably results in the disruption of the pelvic plexus, with both cadaveric and operative dissections of the plexus pathway demonstrating its susceptible nature during rectal resection [199,200]. The courses of the pelvic nerves are as follows:

From the inferior hypogastric plexus, it has multiple branches forming a weblike complex within the endopelvic fascial sleeve, some of which innervate the bladder detrusor.
A main branch traveling inferolateral to the rectum remains deep to the fascia of the levator ani muscle and courses to the external urinary sphincter.
At the level of the bladder neck in females, this pelvic nerve branch sends direct branches to the urinary sphincter [201].

As a result of this course, this has been associated with significant lower urinary tract dysfunction as an operative complication [202]. The reported rate of urinary retention following APR ranges from 25% to 90%, with urinary tract infection frequently being associated [202,203].

Prior studies reveal evidence of sympathetic denervation in 100%, parasympathetic denervation in 38%, and pudendal denervation in 54% of patients postoperatively [1]. The postoperative voiding dysfunction is usually transitory, although sphincteric insufficiency may be permanent [204]. Post-APR urinary retention is best managed by clean intermittent self-catheterization.

Radical Hysterectomy

A similar effect on the lower urinary tract is seen from radical hysterectomy as in APR due to the similar dissection necessitated during the operation and bilateral pelvic lymphadenectomy. However, the location of the plexus inferolateral to the rectum reduces the disruption of the parasympathetic nerve fibers during hysterectomy, and the extent of pericervical dissection (e.g., “nerve-sparing” approach) does not appear to affect the postoperative urinary symptom complex [205]. Persistent postoperative lower urinary tract dysfunction is best managed with a combination of anticholinergic therapy to decrease intravesical storage pressure and catheterization for retention, with most oncologists leaving the patients catheterized for a minimum of 1 week postoperatively. The incidence of fistula is also increased by the radical dissection compared to those hysterectomies for benign indications.

Diabetic Cystopathy

Diabetes mellitus is the most prevalent medical condition resulting in sensory neurogenic lower urinary tract dysfunction affecting 2% of the U.S. population [1,206,207]. Voiding symptoms generally develop at least 10 years after the onset of the disease, as a result of one of three types of neuropathy: peripheral neuropathy, mononeuritis multiplex, and autonomic neuropathy [91,208]. Metabolic abnormalities of Schwann cell function result in segmental demyelinization and subsequent axonal degeneration, impairing nerve conduction [209,210].

Clinical and Urodynamic Features

Diabetes contributes significantly to voiding dysfunction in women [211]. Gradual development of impaired bladder sensation is the first sign, usually associated with other sensory impairments consistent with peripheral neuropathy. Decreased sensation leads to increased intervoiding intervals, which cause an increase in bladder capacity. Eventually, the bladder may become progressively overdistended, impairing contractility and leading to incomplete emptying [212]. Subsequently, symptoms associated with traditional “diabetic cystopathy” may include urinary hesitancy, slowing of the urine stream, and decreasing urinary frequency [211,213]. These symptoms may progress to include a sensation of incomplete emptying or even urinary dribbling from overflow incontinence [211,214].

When questioned, up to 50% of unselected diabetes mellitus patients have subjective evidence of traditional diabetic cystopathy. The urodynamic evaluation, however, suggests alterations in lower urinary tract function in only 27%–85% of these patients [214,215]. Urodynamic studies frequently reveal impaired bladder sensation, increased cystometric bladder capacity, decreased detrusor contractility, an impaired urine flow, and an elevated postvoid residual urine volume [91]. However, more recent studies suggest that DO rather than the “traditional diabetic cystopathy” may be the most common observed voiding dysfunction in patients with diabetes. Kaplan and Te reported on another group of patients with diabetes referred because of voiding symptoms. Of this group, 55% were found to have DO, 23% impaired detrusor contractility, 10% detrusor areflexia, and 11% “indeterminate findings.” In the 42 patients in this group with sacral cord neurological signs, 50% had impaired detrusor contractility and 24% had detrusor areflexia [216]. In addition, poor diabetic control will contribute to urgency and frequency as a result of decreased warning time from impaired sensation and polyuria from the elevated glucose.

Upper tract changes depend upon the duration and severity of the disease process as well as the effect on intravesical pressure. The effect of diabetes-induced lower urinary tract dysfunction on the upper urinary tract is difficult to determine because of the other effects of diabetes on renal function [1]. When managing patients with diabetic cystopathy, preservation of renal function is paramount. A direct effect of diabetes on renal microvasculature, combined with upper tract obstructive changes resulting from diabetic cystopathy, put the diabetic kidneys at great risk. A timed voiding schedule is effective in those with impaired contractility, while intermittent catheterization is reserved for those who experience greater difficulty with emptying. Anticholinergic therapy may be effective for those with DO or impaired bladder compliance [207].

CONCLUSIONS

While neurological conditions are frequently associated with lower urinary tract dysfunction, clinicians often overlook neurological etiologies during workup and treatment of voiding dysfunctions. A high index of suspicion should be maintained where the severity of symptoms is disproportionately high or in rapid onset of symptoms. A brief neurological examination at the time of presentation of new patients —or during urodynamic—should be considered as a standard for good practice. Management of voiding dysfunction in patients with neurological comorbidities requires consideration of functional disabilities and other medications.

53 Nonneurogenic Voiding Dysfunction and Urinary Retention

Bernard T. Haylen

INTRODUCTION

One of the core aims of the clinical and urodynamic assessment of women with symptoms of pelvic floor dysfunction is to screen for the presence of voiding dysfunction (VD), i.e., abnormally slow and/or incomplete micturition [1]. Clinical assessment may provide limited, generally nonspecific information with two screening urodynamic tests, uroflowmetry and a postvoid residual (PVR) measurement of much greater value. Uroflowmetry, or the measure of urine flow over time, allows the simple and noninvasive analysis of the normality or otherwise of urine flow while the complementary measurement of PVR will indicate the completeness or otherwise of micturition.

Abnormal urine flow rates or patterns or high PVRs in women will generally require the further investigation of voiding cystometry in order to determine the cause. Pressure and flow analysis will assist the discrimination between the presence of one of the two main causes of abnormally slow urine flow, i.e., bladder outflow obstruction and a hypotonic or atonic bladder.

It is important clinically to diagnose or eliminate the diagnosis of VD in women presenting for assessment of symptoms of pelvic floor dysfunction. Surgical treatment of urodynamic stress incontinence (USI) and drug treatment of detrusor overactivity (DO) both have the potential to cause VD. Preexisting VD will prejudice these treatments, leading to the possibility of acute or chronic retention.

The subsequent discussion will focus on women not presenting with existing neurological disorders known to be associated with VD.

CLINICAL ASSESSMENT

Symptoms of VD should be included in a comprehensive history in women presenting with symptoms of pelvic floor dysfunction. The Standardization and Terminology Committees of the International Continence Society (ICS) and the International Urogynecological Association [1] have suggested the following definitions for “voiding and postmicturition symptoms”:

Voiding and postmicturition symptoms: A departure from normal sensation or function experienced by the patient during or following the act of micturition.

Hesitancy: Complaint of a delay in initiating micturition.

Slow stream: Complaint of a urinary stream perceived as slower compared to previous performance or in comparison with others.

Intermittency: Complaint of urine flow that stops and starts on one or more occasions during voiding.

Straining to void: Complaint of the need to make an intensive effort (by abdominal straining, Valsalva, or suprapubic pressure) to either initiate, maintain, or improve the urinary stream.

Spraying (splitting) of urinary stream: Complaint that the urine passage is a spray or split rather than a single discrete stream.

Feeling of incomplete (bladder) emptying: Complaint that the bladder does not feel empty after micturition.

Need to immediately revoid: Complaint that further micturition is necessary soon after passing urine.

Postmicturition leakage: Complaint of a further involuntary passage of urine following the completion of micturition.

Position-dependent micturition: Complaint of having to take specific positions to be able to micturate spontaneously or to improve bladder emptying, e.g., leaning forward or backward on the toilet seat or voiding in the semistanding position.

Dysuria: Complaint of burning or other discomfort during micturition. Discomfort may be intrinsic to the lower urinary tract or external (vulvar dysuria).
Urinary retention: Complaint of inability to pass urine despite persistent effort.

These symptoms are mostly nonspecific and not diagnostic in themselves though the symptoms of hesitancy, a poor stream, and straining to void have been more commonly linked to an abnormally slow urine flow rate or a high PVR [2].

Of the various clinical signs, that of uterine and/or vaginal prolapse, particularly if higher stage, can be associated with a diagnosis of VD by a urethral "kinking effect." Atrophic vaginal changes might be an indicator that atrophic urethral changes might be present causing a possible "stenotic" effect.

HISTORY OF UROFLOWMETRY

The first attempt to obtain an objective measurement of the urine flow rate was made in 1897 by Rehfisch [3] (Ryall and Marshall [4]) using a poorly detailed method employing an air displacement principle. Ballenger et al. [5] felt that the cast distance of urinary stream (voiding distance) might be a useful clinical guide to the presence of prostatic disease.

Drake [6] made the first accurate measurements of urine flow. He used a spring balance; a pen that wrote on a kymograph was attached to one end, and a receptacle for the voided volume was attached to the other end. By rotating the kymograph drawn at a known speed, Drake obtained a trace of voided urine volume against time. He calculated the maximum urine flow rate by a measurement of the steepest part of the volume–time curve. It is evident from his description that the apparatus was relatively crude and difficult to use. Furthermore, urine flow rates had to be calculated from volume–time data. Drake's flowmeter was never produced commercially. Kaufman [7] commercially produced a modification of Drake's flowmeter that was more refined but similarly made no direct recording of flow rate.

The advent of electronics in medical instrumentation allowed the mass production of accurate and reliable recording devices. Von Garrelts [8] designed the first of the electronic urine flowmeters, which consisted of a tall urine-collecting cylinder with a pressure transducer in the base. The pressure transducer measured the pressure exerted by an increasing column of urine as the patient voided. Since a direct relationship existed between the volume voided and the pressure recorded, von Garrelts was able to produce a direct recording of urine flow rate by electronic differentiation with time.

In 2016, it is 39 years since it was determined that uroflowmeters of acceptable accuracy were available [9]. The current accuracy of modern uroflowmeters is around ±2%–5%, despite the fact that a variety of different physical principles are currently used. Regular calibration of the uroflowmeter is required to maintain accuracy.

DEFINITION OF URINE FLOW RATE MEASUREMENTS

In any field of scientific measurement, it is important that all workers use standardized terminology. Urine flow rates are measured in milliliters per second (mL/s). Figure 53.1 denotes the definitions for urine flow rate measurements as suggested by the Standardization and Terminology Committees of ICS and IUGA [1]:

Urine flow: Voluntary urethral passage of urine, which may be
Continuous: No interruption to flow.
Intermittent: Flow is interrupted.
Flow rate: Volume of urine expelled via the urethra per unit time. It is expressed in mL/s.
Voided volume (*mL*): Total volume of urine expelled via the urethra.
Maximum flow rate (*MUFR–mL/s*)–Q_{max}: Maximum measured value of the flow rate correcting for artifacts.
Flow time (*second*): The time over which measurable flow actually occurs.
Average (urine) flow rate (*AUFR–mL/s*)–Q_{ave}: Voided volume divided by the flow time. It may be calculated from the area beneath the flow time curve.
Voiding time (*second*): This is the total duration of micturition, which includes interruptions. When voiding is completed without interruption, voiding time is equal to flow time.
Time to maximum flow (*second*): This is the elapsed time from the onset of urine flow to maximum

urine flow.

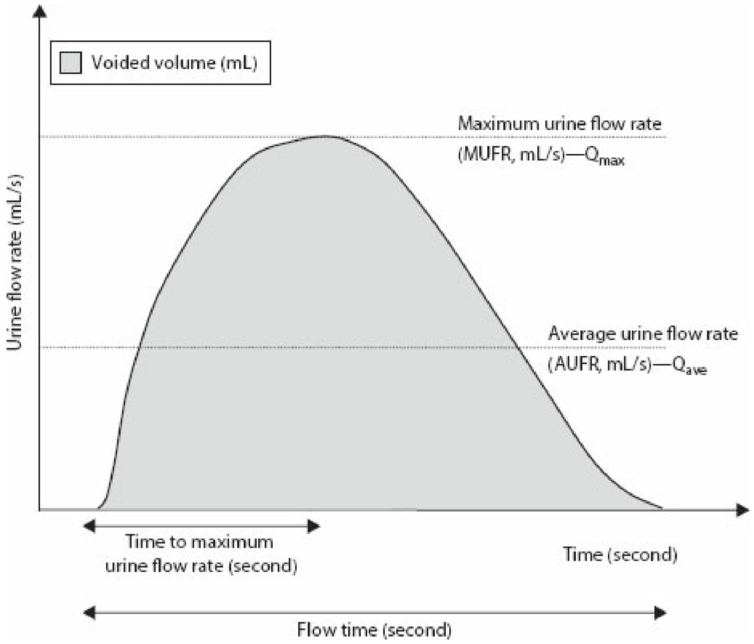

Figure 53.1 A schematic representation of urine flow over time.

Figure 53.1 shows a schematic representation of urine flow over time.

METHODS OF URINE FLOW RATE MEASUREMENT

Numerous physical principles have been employed over the years in an attempt to develop what Backman [10] and Von Garrelts and Strandell [11] would see as an ideal uroflowmeter:

1. High level of accuracy at different voided volumes and urine flow rates
2. Easy to read and rapidly available permanent tracings
3. Unobtrusive and not distracting to the patient by appearance or sound
4. Easy to clean

There have been many methods used for urine flow measurement, from measuring the time to void a given volume through audiometric and radioisotopic methods to even include high-speed cinematography. The most common method has been that of Drake [6] modified by von Garrelts and Strandell [11]—the measurement of urine weight.

In addition, flowmeters have been produced that use the principles of air displacement, differential resistance to gas flow, electromagnetism, photoelectricity, electrical capacitance, and a rotating disc.

Flowmeters employing the principles of weight transduction, a rotating disc, and a capacitance transducer are the best known and the most completely tested and validated of the flowmeters available.

The weight transducer type of flowmeter weighs the voided urine and by differentiation with time produces an “online” recording of urine flow rate:

$$FR = dVdT$$

where dV is the change in volume of urine over change in time, dt.

The rotating disc flowmeter depends on a servometer maintaining the rotation of the disc at a constant speed. Urine hits the disc, and the extra power required to maintain the speed is electronically converted into a measurement of flow rate.

The capacitance flowmeter is the simplest of the three flowmeters. This flowmeter consists of a funnel leading urine into a collecting vessel. The transducer is in the form of a dipstick made of plastic and coated with metal, which dips into the vessel containing the voided urine.

All three types of flowmeter perform accurately and efficiently. For clinical purposes, the measured and indicated flow rate should be accurate to within ±5% more than the clinically significant flow rate range [12]. The capacitance (dipstick) flowmeter is the least expensive to buy and has the advantage of no moving parts, which means mechanical breakdowns are eliminated. Rotating disc flowmeters have the advantage of not requiring priming with fluid. Automatic start and stop facilities in some modern flowmeters assist by minimizing patient and staff involvement during the uroflowmetry (Figure 53.2).

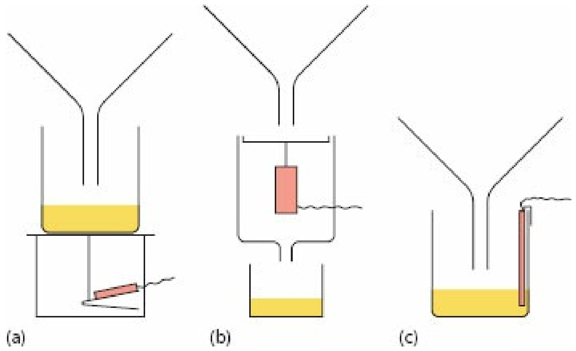

Figure 53.2 Urine flowmeters: (a) weight transducer, (b) rotating disc, and (c) capacitance (dipstick).

CLINICAL MEASUREMENT OF URINE FLOW RATES

The environment for patient flow rate recording is of considerable importance. Female patients usually void in circumstances of almost complete privacy. It is essential in the clinical situation that every effort is made to make the patient feel comfortable and relaxed. If these requirements are ignored, psychological factors are introduced and a higher proportion of patients will fail to void in a representative way. Ideally, all free uroflowmetry studies should be performed in a completely private uroflowmetry room/toilet, lockable from the inside, and out of hearing range of other staff and patients. As crouching over a toilet seat causes a 21% reduction in the average urine flow rate [13], patients should be encouraged to sit to void. When video studies are combined with pressure–flow recordings in a radiology department, up to 30% of women may fail to void.

Patients should be encouraged to attend for uroflowmetry with their bladder comfortably full. It is desirable that the measured urine flow rates should be for a voided volume within the patient’s normal range. This range can be determined if, in the week before the flow study, the patient completes a frequency–volume chart (urinary diary). On this chart, the patient enters the volumes of fluid consumed and the volumes of urine voided. Recent nomograms, however, provide normal reference ranges for urinary flow rates over a wide range of voided volumes. There is generally no need for multiple uroflowmetry in most women. Abnormal or unusual flow curves and urinary flow rates, however, merit repeating the study.

URINE FLOW RATES IN NORMAL (ASYMPTOMATIC) WOMEN

The maximum and average urinary flow rates are the two most important uroflowmetry parameters. They are both numerical representations of the urine flow curve. The clinical usefulness of flow rates had been attenuated by the lack of absolute values defining normal limits [14]. As urinary flow rates are known to have a strong dependence on voided volume [6,15], these normal limits need to be over a wide range of voided volumes, ideally in the form of nomograms.

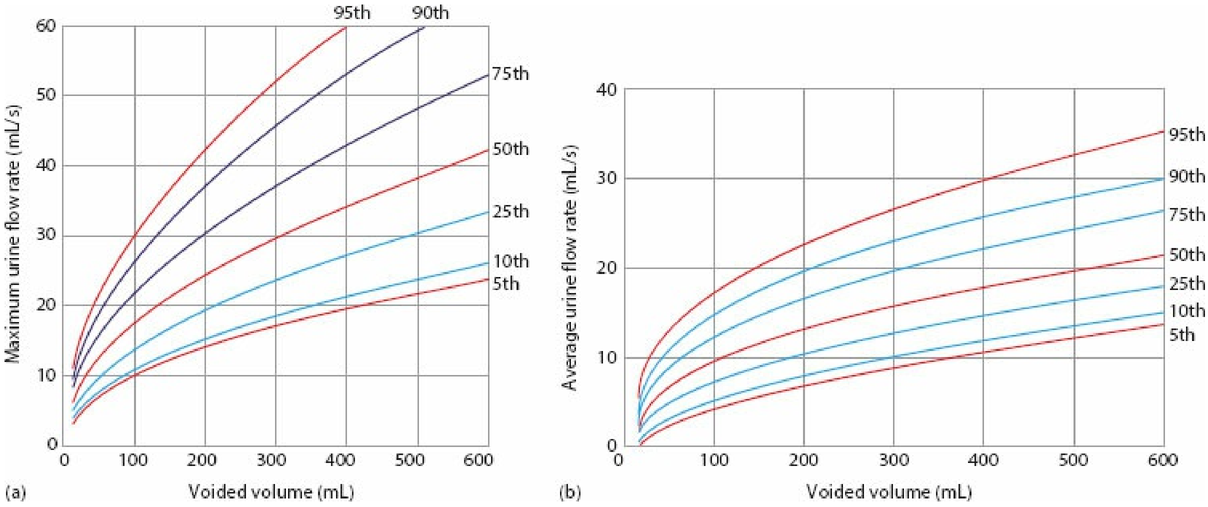

Figure 53.3 (a) Liverpool nomogram for maximum urine flow rate in women. (b) Liverpool nomogram for average urine flow rate in women.

Studies on normal values for urinary flow rates in women include those of Peter and Drake [16], Scott and McIhlaney [17], Backman [18], Susset et al. [19], Walter et al. [20], Drach et al. [15], Bottacini and Gleason [21], Fantl et al. [22], and Rollema [23]. Data and/or statistical analysis in these studies has not allowed effective nomogram construction. Study restrictions have included small patient numbers [19–23]; the use of outmoded or less well-evaluated equipment [15–16] and the incompleteness of data at lower voided volumes [15,18] due in part to the inaccuracy of some equipment at lower voided volumes [15].

In a 1989 study, Haylen et al. [24] studied 249 female volunteers (aged 16–63 years), all of whom were deemed normal by denying specific urinary symptomatology, underwent uroflowmetry studies. Each woman voided once in a completely private environment over a calibrated rotating disc-type uroflowmeter; 46 voided on a second occasion. The maximum and average flow rates of the first voids were compared with the respective voided volumes. By using statistical transformations of both voided volumes and urine flow rates, relationships between the two variables were obtained. This allowed the construction of nomograms, which, for ease of interpretation, have been displayed in centile form (Figure 53.3):

$$\text{Ln(MUFR)} = 0.511 + 0.505 \times \text{Ln(voided volume)}$$

$$\text{Root mean square error} = 0.340^{*}$$

More recently, Barapatre et al. [25] produced nomograms using the data of 343 healthy Indian women. The results, after elimination of “abnormal” data, were much slower urine flow rates overall than those in the Liverpool nomograms and an age dependency of urine flow rates, not normally noted in asymptomatic women [15,22,24,26]. As noted later, their median centiles in asymptomatic women were slower than the studies using the Liverpool nomograms in symptomatic women:

$$\text{Square root(AUFR)} = -0.921 + 0.869 \times \text{Ln(Voided Volume)}$$

$$\text{Root mean square error} = 0.640^{\dagger}$$

Traditional “cutoff” values for normal urine flow rates have been used with due scientific analysis of their accuracy or value. The maximum urine flow rate has been most studied. Recommended lower limits of normality range between 12 and 20 mL/s. Most commonly, a minimum rate of 15 mL per second is quoted for the same parameter if at least 150 mL (or sometimes 200 mL) has been voided. The practice of artificially imposing minimum limits for the voided volume is difficult to justify [27] and very often impractical. Women with certain states of lower urinary tract dysfunction, those in whom the flow rate might be most important, may not be able to hold 200 mL. It has been demonstrated that only 45% of voided volumes are more than 200 mL and 55% are more than 150 mL, making interpretation of fixed urine flow rates valid [28]. Because of the strong dependency of urine flow rates on a voided volume, a normal urine flow rate at 200 mL may not also be normal at 400 mL.

CLINICAL FACTORS INFLUENCING URINE FLOW RATES IN NORMAL (ASYMPTOMATIC) WOMEN

Voided Volume

The use of nomograms overcomes the dangers of referencing flow rates to any one voided volume. A maximum flow rate of 15 mL/s might fall just within the fifth centile curve at 200 mL voided volume, though well below the same curve at 400 mL. The median voided volume of 171 and 175 mL in the aforementioned series [24,28] again highlights the need for normal reference ranges to include data at lower voided volumes.

Both the maximum and average urine flow rates in the aforementioned study were found to have a strong and essentially equal dependence on voided volume. The clinical use of either flow rate is equally valid. However, the centile lines onto which the maximum and average urine flow rates respectively fall for the same voided volume (centile rankings) are not interchangeable in an individual instance due to wide variations in urine flow patterns. The closer the urine flow pattern comes to the "ideal" flow time curve seen in Figure 53.1, the more chance there will be that the centile rankings for the maximum and average urine flow rates are the same.

No systematic deterioration of either flow rate at higher voided volumes was discernible from this population study. The same may not be true for an individual.

Age and Parity

Drach et al. [15], Fantl et al. [22], and Haylen et al. [24] found no significant age dependence of urinary flow rates in normal women, unlike the findings of Barapatre et al. [25]. The same studies also found that there was no significant effect of parity on urine flow rates in normal women. This was not tested by Barapatre et al. [25].

Repeated Voiding

There was a remarkable consistency in the centile rankings of the paired first and second voids in the study of Haylen et al. [24]. This consistency is further witnessed in the multiple voids from a single 25-year-old normal female volunteer (Figure 53.4). Fantl et al. [22] found no significant difference between the first and up to the sixth void in the 60 women they tested. This was not tested by Barapatre et al. [25]. Clinically, in the majority of normal women, the centile rankings of successive voids will not differ widely. It is uncertain, at present, whether this is also true for women with lower urinary tract dysfunction. As suggested previously, abnormal or unusual flow rates or curves merit repeating the study.

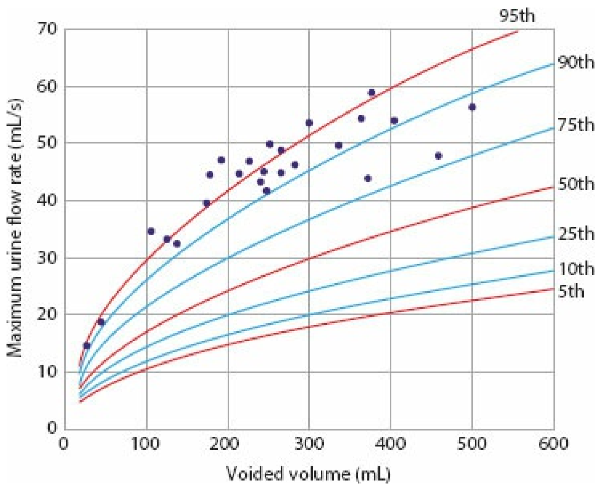

Figure 53.4 The maximum flow rates from a large number of voids by a single 25-year-old female volunteer superimposed on the respective Liverpool nomogram.

Presence of a Catheter

The aforementioned nomograms refer to free flowmetry voids; they are not applicable where pressure of another catheter is present in the urethra. All urethral catheters can be expected to have the effect of decreasing urinary flow rates for the equivalent voided volume. Part of this reduction is physical obstruction with pressure catheters varying from 6 FG (microtranducer) to 10 FG (water-filled). By necessity, potentially unfavorable environmental and psychological factors are introduced when catheterization flowmetry is performed. Ryall and Marshall [29] suggested that the reduction is maximum urinary flow rate caused by the fine (diameter = 2 mm) urethral catheter used in their study of 147 symptomatic men was of the order of several mL/sec. Though small, this reduction was enough to change the diagnostic categorization of one-third of their subjects.

Normal Male vs. Normal Female Urine Flow Rates

Female urine flow rates are higher than those of men [10,15,24]. Female maximum urine flow rates are on average 0.19 times greater than those of young men and 0.39 times greater than the older men [24]. Urethral length (4 cm vs. 20 cm) should account for all the intersex difference [10,24].

URINE FLOW RATES IN WOMEN WITH SYMPTOMS OF PELVIC FLOOR DYSFUNCTION

Between 1958 and 1990, there were four studies on urine flow rates in symptomatic women (those with symptoms of pelvic floor dysfunction), three of which were small [15,16,21]. The other study [30] was limited to the effect of final urodynamic diagnosis on urine flow rates. Three studies indicated that symptomatic women had slower urine flow rates than normal women with one study [15] showing no difference. In 1995, Haylen et al. [31] completed a study of 250 women who were consecutive referrals for urogynecological assessment with symptoms of pelvic floor dysfunction. The flow data for these women were converted to centiles from the Liverpool Nomograms for the following analyses of their median values:

A Comparison of the Urine Flow Rates of Symptomatic and Asymptomatic Women

Table 53.1 shows that the median centiles of the maximum and average urine flow rates of the urogynecology (symptomatic) patients were significantly reduced from those of the asymptomatic population. There was a close agreement between the studies with the 1990 study [30] performed in a different country to the 1995 study [31].

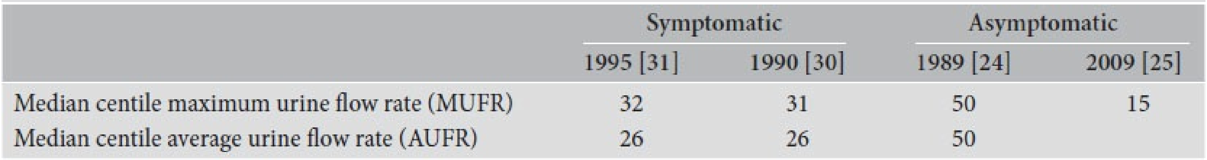

Table 53.1 Comparison of Urine Flow Rates of Symptomatic and Asymptomatic Women

	Symptomatic		Asymptomatic	
	1995 [31]	1990 [30]	1989 [24]	2009 [25]
Median centile maximum urine flow rate (MUFR)	32	31	50	15
Median centile average urine flow rate (AUFR)	26	26	50	

As noted, Barapatre et al.'s [25] 2009 study gives results for urine flow rate centiles in asymptomatic women far slower than equivalent studies in symptomatic women.

Effect of the Presence of Genital Prolapse on Urine Flow Rates in Symptomatic Women

A generally progressive decline in the maximum and average urine flow rates (median centiles) of symptomatic women [31] with increasing grades of genital prolapse was noted. The most significant decline occurred in the presence of uterine prolapse closely followed by cystocoele and enterocoele. More recent data [32], however, would suggest the significance of this may be lost in multivariate analysis of a much larger cohort of symptomatic women.

Effect of Prior Hysterectomy on Urine Flow Rates in Symptomatic Women

A significant decline in the urine flow rates [31] of symptomatic women (median centiles) in the presence of a prior hysterectomy. The effect was the same with both vaginal and abdominal hysterectomy. The flow rates for those symptomatic women without prior hysterectomy was found to be the same as that for the asymptomatic female population. Further analysis suggests that in women with both prior hysterectomy and intercurrent genital prolapse, there is a cumulative decline in urine flow. More recent data [32], however, would suggest the significance of this may be lost in multivariate analysis of a much larger cohort of symptomatic women.

Effect of Age and Parity on Urine Flow Rates in Symptomatic Women

Unlike asymptomatic women, there is a significant effect of age on the maximum and average urine flow rates [30,31]. More recent data [32] suggest that age is the main association of abnormally slow urine flow rates in a large cohort of symptomatic women. Parity was not found to be a significant factor in either this or the 1999 study [31].

Effect of Final Urodynamic Diagnosis on the Urine Flow Rates of Symptomatic Women

Median urine flow rate centiles of the urogynecology patients separated according to the final urodynamic diagnosis are given in Table 53.2.

All categories of diagnoses have their median centiles under those for the normal female population (50 by definition).

VD appears to be the diagnosis for which urine flow rates might have the best discriminatory ability. Further analysis shows that the *10th centile of the Liverpool nomogram* [28,30,31] for the maximum urine flow rate has the best discriminatory ability (sensitivity 81%, specificity 92%) with respect to diagnosing the presence or absence of the final diagnosis of VD either as a solitary or a mixed diagnosis.

Table 53.2 Effect of Final Urodynamic Diagnosis on the Urine Flow Rates of Symptomatic Women

Diagnosis	**Number**	**MUFR**	**AUFR**
USI	107	48	40
DO	14	38	32
VD	7	1	6
USI plus DO	39	34	32
USI plus VD	22	3	2
DO plus VD	14	3	2
USI plus VD plus DO	10	4	7
Normal	7	70	52

More recent data [32] on a large cohort of symptomatic women again showed the highest urine flow rate centiles in women with USI and DO and the lowest in women with VD.

OTHER FACTORS INFLUENCING URINE FLOW RATES

Urine flow depends on the relationship between the bladder and urethra during voiding. The situation during voiding is the antithesis of the situation required for continence. Continence depends on intraurethral pressure being higher than intravesical pressure. For voiding to occur, intravesical pressure must exceed intraurethral pressure.

Einhorning [33] and later Asmusen and Ulmsten [34] showed clearly that before any rise in intravesical pressure, a fall in intraurethral pressure occurred. This suggests that the urethra actively relaxes during voiding rather than being passively “blown open” by the detrusor contraction. Soon after the urethra has relaxed and pelvic floor descent has occurred, the detrusor contracts. The detrusor normally contrives to contract until the bladder is empty, producing a continuous flow curve. Many women void by urethral relaxation alone with minimal or no detrusor involvement. This method of voiding is common in women with USI.

Changes in intra-abdominal pressure also influence urine flow. Some women appear to void entirely by increasing intra-abdominal pressure, that is, by contraction of the diaphragm and anterior abdominal wall muscles.

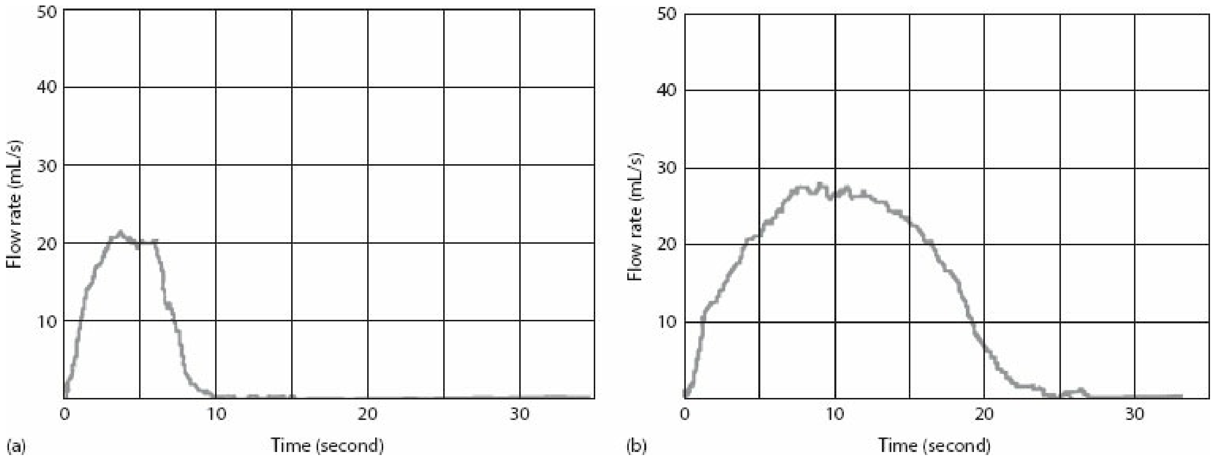

Figure 53.5 Normal flow curves for voided volumes of (a) 121 mL and (b) 345 mL.

It follows from this discussion that the urine flow may differ from normal as a result of abnormalities of the urethra or the detrusor.

Urethral Factors

Anatomical factors

The urethra may be abnormally narrow or the urethra may not be straight. The narrowest part of the urethra, as shown by video studies of voiding, is usually the midzone. However, the urethra may become narrowed and the most common site is at the external meatus associated with estrogen deficiency in the postmenopausal women. Bladder neck obstruction in the female had been thought to be extremely rare [35]. The female urethra is usually straight, and deviation from this state is most common in anterior vaginal wall prolapse and higher degrees of uterine and vaginal vault prolapse. Data earlier point to a possible adverse effect of such prolapse on urine flow rates. The prolapse and urethral effects make bladder outflow obstruction not that uncommon in women.

Pathological Factors

Unusual congenital conditions such as urethral duplications, urethral diverticula, or urethral cysts may obstruct voiding. Infective lesions as in urethritis or infected paraurethral cysts may lead to voiding difficulties. Post-traumatic strictures and urethral neoplasms will have a similar effect. Intravaginal abnormalities, such as prolapse or foreign bodies, may also obstruct micturition.

Functional Factors

Abnormal urethral behavior during voiding may lead to alteration in the urine flow rate recording. Urethral closure may be due to contraction of the intraurethral striated muscle or to contraction of the pelvic floor. In the neurologically abnormal patient, contraction of the intraurethral striated muscle with or without the pelvic floor is known as detrusor sphincter dyssynergia. In the nervous and anxious but neurologically normal patient, the urethra may be closed by pelvic floor contraction.

Detrusor Factors

Contractility

It is well known that when neurological disease occurs, bladder behavior may be altered. However, in patients with no neurological disease, poor detrusor contractility may be responsible for a slow flow rate. Such patients may have UTIs or urinary retention. These patients have normal urethral function as judged by urethral pressure profilometry or radiology. Their reduced flow rates are secondary to a weak and poorly sustained detrusor contraction. A proportion of this clinical group goes on to demonstrate classical neurological diseases such as multiple sclerosis.

Innervation

Normal detrusor behavior depends on normal innervation. Bladder contractions are preserved if the sacral reflex arc is intact even when the upper motor neurons are damaged. However, if the sacral reflex arc is damaged, bladder contractions are generally absent. The only form of contractile activity possible when the lower motor neuron is damaged is locally mediated—the “autonomous” bladder. The urine flow rates produced by the abnormally innervated bladder are usually reduced and interrupted.

Pathological Factors

Although little specific literature on the subject exists, it is evident that gross disease of the detrusor will result in abnormal urine flow rates. The fibrosis resulting from irradiation, tuberculosis, cystitis, or interstitial cystitis is likely to impair detrusor contractility

URINARY FLOW PATTERNS

Urine flow curves are complementary to flow rates in the assessment of voiding. Because flow curves cannot be numerically represented (except by urine flow rates), they are less useful for clinical comparisons than flow rates. Several patterns of flow curves can however be recognized.

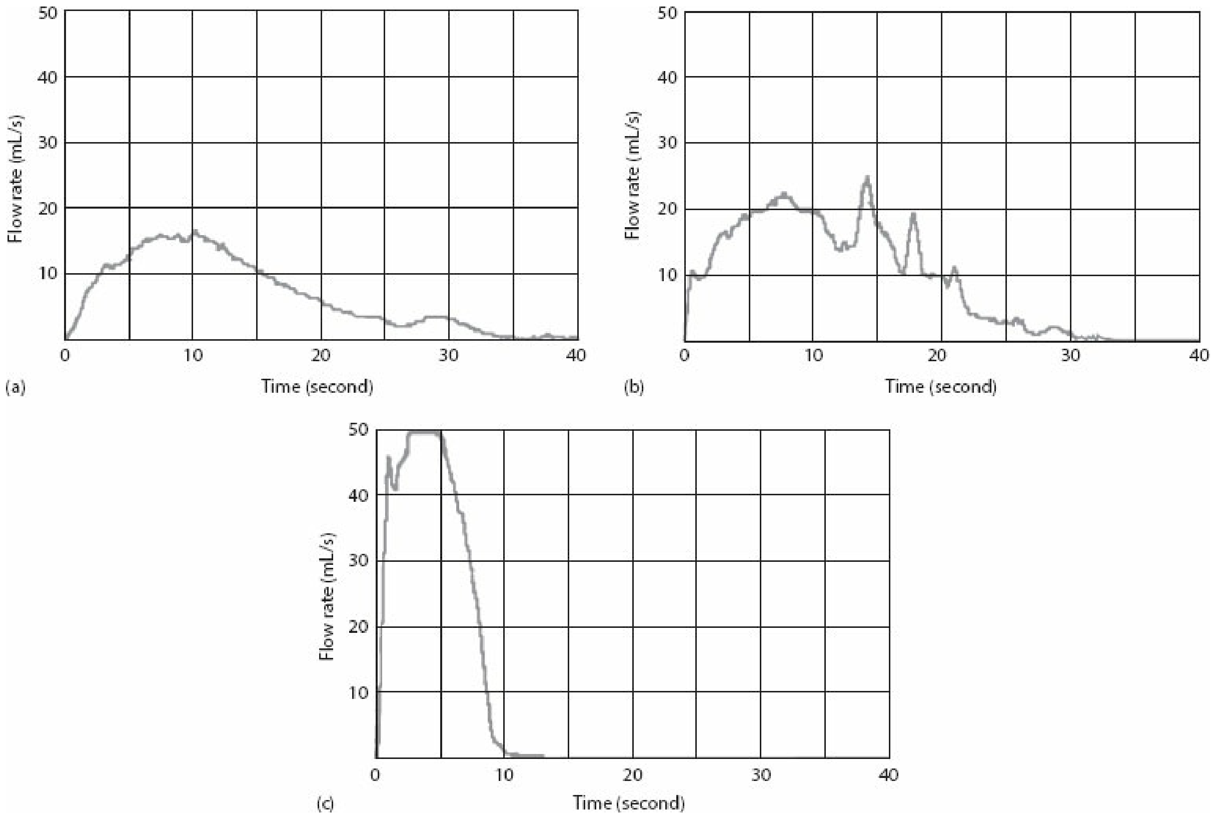

Figure 53.6 (a) low normal (suboptimal) flow curve (voided volume 261 mL), (b) abdominal strain pattern (voided volume 353 mL), (c) high takeoff flow pattern (voided volume 336 mL).

Normal

The normal flow trace (Figure 53.5a and b) shows a symmetrical peak with a maximum flow rate generally achieved within 5 seconds of the beginning of voiding. The maximum flow rate is generally 1.5–2 times the average flow rate.

A low normal (suboptimal) flow trace (Figure 53.6a) shows no symmetrical peak. Maximum flow rate, somewhere between the 5th and 25th centile, occurs early, and then the flow trails off. An abdominal strain pattern (Figure 53.6b) shows the influence of generally intermittent abdominal strain during the void. It is manifested by irregular moderately fast accelerations in maximum urine flow. A high takeoff pattern (Figure 53.6c) shows a very rapid acceleration to a high maximum flow rate. A higher incidence of such traces has been noted in both men and women with DO.

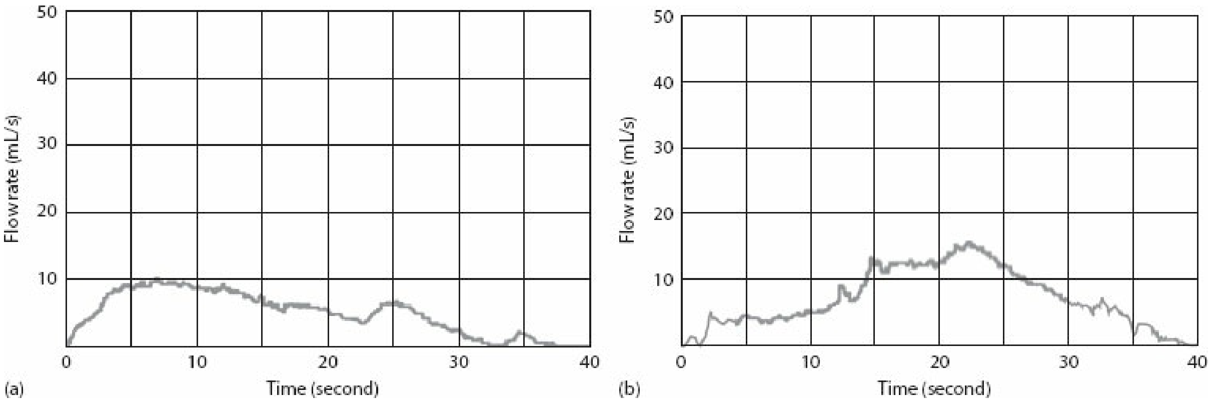

Figure 53.7 Reduced urine flow trace caused by (a) bladder outflow obstruction (maximum detrusor voiding pressure 54 cmH_2O) and (b) detrusor underactivity (maximum detrusor voiding pressure 15 cmH_2O).

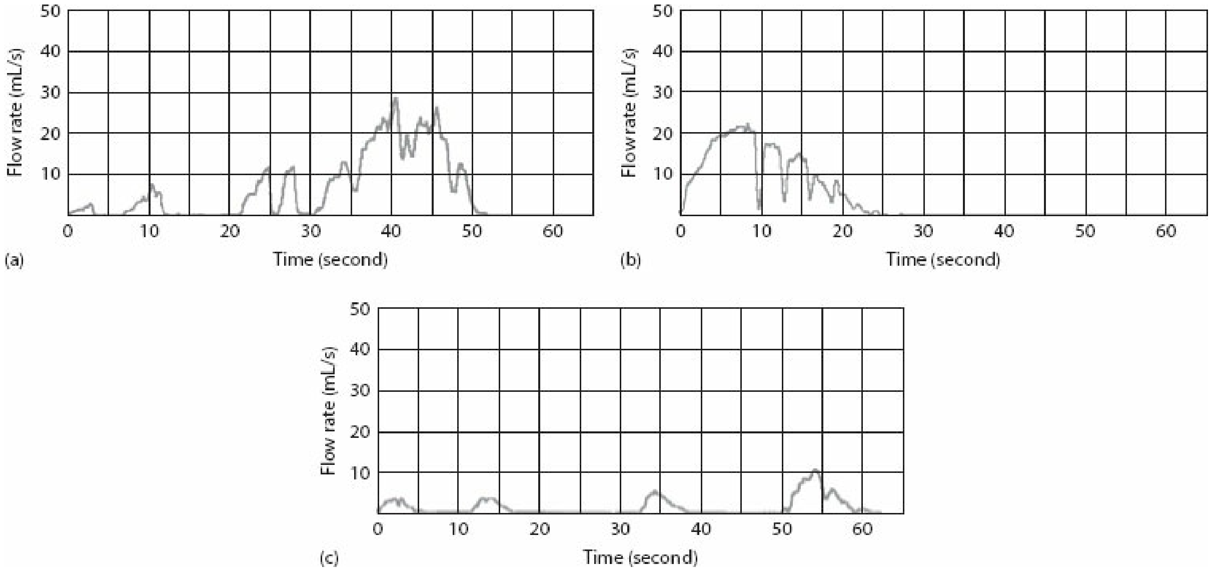

Figure 53.8 (a) Abdominal pressure voiding pattern, (b) voluntary sphincter contraction urine flow pattern, and (c) detrusor sphincter dyssynergia flow pattern.

Abnormal–Continuous Flow

Urine flow curves reflected in flow rates below the 5th centile may generally be regarded as abnormal; abnormality can be suspected in those curves with flow rates between the 5th and 10th centile.

A reduced flow rate may be due either to a urethral obstruction or to a poor detrusor contraction (Figure 53.7a and b). It is necessary to perform full pressure flow studies to demonstrate the cause of a reduced urine flow rate.

Abnormal–Interrupted Flow

An abdominal pressure voiding pattern (Figure 53.8a) is where abdominal straining provides the pressure behind the voiding. Little detrusor activity is present. Irregular interrupted peaks of flow are the result. Maximum urine flow rate is more than twice the average urine flow rate.

A voluntary sphincter contraction urine flow pattern (Figure 53.8b) occurs as the anxious nervous patient closes her distal urethral sphincter mechanism. Flow rate may decrease or stop. Characteristically, the rate of change of flow rate is rapid, indicating sphincter closure. The fluctuations due to detrusor underactivity would be much slower than those seen here.

Detrusor sphincter dyssynergia is an involuntary phenomenon in which the expected coordination of the detrusor contraction and urethral relaxation is lost. Despite an effective detrusor contraction, the urethral mechanism remains closed for longer periods of time (up to several minutes). Detrusor sphincter dyssynergia may result in a large residual urine together with upper tract dilatation and renal failure and is often associated with repeated infection. Detrusor sphincter dyssynergia only occurs in neurologically abnormal patients, most classically in high spinal cord trauma. The flow rate produced by detrusor sphincter dyssynergia (Figure 53.8c) is usually reduced and always interrupted.

POSTVOID RESIDUAL MEASUREMENT

Definition

The PVR is defined as the volume of urine remaining in the bladder at the completion of micturition [1].

Clinical Relevance

The PVR is a key marker of bladder function in terms of emptying ability. An abnormally high PVR, if confirmed by repeat measurement, confirms the presence of VD. Voiding cystometry is needed to assist in determining the cause.

Accuracy of PVR Measurement

The accuracy of PVR measurement has not matched other urodynamic variables such as pressure and flow. Subsequent discussion will show that the best accuracies are around ±25% for methodologies, usually ultrasound, involving immediacy (within 60 seconds). Those techniques (usually catheterization) involving delayed measurement can lead to errors, generally overestimation by, at times, very significant percentages.

Diuresis Factor

The main source of error in PVR measurement is the additional renal input into bladder volume from the delay in PVR measurement following micturition leading to an overestimation. Two factors can be multiplied to determine this input: (1) the diuresis (mL/min) occurring at the time (this can be 1–14 mL/min) [36,37] and (2) the duration of the delay (min) between completion of micturition and PVR measurement (if the latter is by urethral catheterization, the end point of the delay is the completion of bladder drainage). If both are excessive, the overestimation can be marked.

PVR Measurement by Catheterization

Urethral catheterization, the traditional approach to PVR measurement, is most vulnerable to the *diuresis factor*, as it takes 4.5 minutes minimum in studies [36,37] from the completion of micturition to the completion of bladder drainage using a catheter. Other factors are relevant:

Catheter Factor

For PVR measurement by urethral catheterization, the use of a catheter, which incompletely drains the bladder, will lead to an underestimation of the true PVR. A short plastic catheter (particularly a 14 FG though a 12 FG is probably also adequate) will make sure [37,38] that whatever PVR present will be completely drained (under 1 mL postcatheterization bladder volume). A 14 FG Foley urethral catheter will leave, on average, 77 mL of postcatheterization bladder volume [38,39]. Smaller Foley catheters than 14 FG can be expected to have an even higher postcatheterization bladder volume.

It is a quoted practice to enhance the drainage of a Foley catheter by suction drainage using a syringe. While there is weak evidence that this might be helpful [39], the efficacy of this technique has not been proven. Similarly, small-bore urodynamic filling catheters have been used to drain the bladder, though this may be relatively slow, thus increasing the delay in collection. There are no published data to confirm their efficacy in bladder drainage.

Measurement Apparatus Factor

Presuming the PVR collection occurs without delay, a catheter with known efficacy in bladder drainage is used and there is no PVR spillage; one has to rely on the accuracy of the measuring apparatus used, which might have variable and often inappropriate (for the volume) and inaccurate calibration.

PVR Measurement by Ultrasound

Accuracy

Ultrasound techniques of known accuracy offer the best prospects of minimizing the aforementioned inaccuracies in PVR measurement, allowing cost considerations. The benefits of ultrasound for PVR measurement (known accuracy, reduced time, and patient trauma) need to be added to the increasing array of other indications for ultrasound in urogynecology (bladder neck assessment and intercurrent lower urinary tract and pelvic floor pathology [40]) when equipment costs are being considered. With ultrasound, all women with any PVR have the opportunity of a second attempt to reduce or clear this volume. This might avoid the need for subsequent repeat PVR measurements if surgery was being contemplated in a patient with an abnormally high PVR measured using urethral catheterization.

Abdominal Ultrasound

The use of this modality to measure bladder volumes dates back to 1967 [41]. Different formulae have been used generally, using three bladder dimensions, height, width, and depth (generally multiplied by a constant, with 0.625 commonly used [42]). Results have been variable and conflicting [42] with accuracies limited by the variability in bladder shape and filling [43]. Accuracies in most published series are around 21%–25% [41–43]. The key limitation of transabdominal ultrasound is the distance between the abdominal wall and the bladder, with fat (obesity), gas, and bone (shadowing of the pubis) potential impediments to the transmission of the sound beam. Smaller bladder volumes (under 100 mL) have been cited as more difficult to quantify with false negatives occurring under 50 mL [42]. Advances in ultrasound technology will have improved visualization over time.

Transvaginal Ultrasound

This modality, first reported in 1989 [44], involves the calculation of bladder volumes using two bladder dimensions in the sagittal plane. It has been shown to provide accurate and validated [45] measurements of PVRs from 0 to 175 mL with superior visualization of PVR under 30 mL, where around 80% to 90% of PVR appear likely to occur [46,47]. Accuracy is 24% (overall) and 15% (volumes 50 mL and over). Under 50 mL, the accuracy rises to 55%. Transrectal ultrasound was also reported in 1989 [48], using similar methodology to that for transvaginal ultrasound with a mean accuracy of 16%. Although its calibration was done only in men, it is possible to measure PVRs in women accurately using this modality. The accuracy of transperineal (translabial) ultrasound in PVR measurement [49] has been researched and found to be almost identical to that of transvaginal ultrasound [44]. This modality is already used widely in urogynecology [40], with perhaps less specialized probes than what is used with transvaginal or transrectal ultrasound.

Doppler Planimetry

This alternate form of abdominal ultrasound has gained popularity in measuring PVRs. Commercial application had started in 1986 [50] with an early report in 1996 [51]. The systems are small and portable with the technique for use quickly learned. Cross-sectional planes of the bladder are measured at 15° angular increments with a computer software constructing a 3D model of the bladder from which volume is determined. This form of PVR assessment has been shown to be accurate within 15% of bladder volumes as measured by a urethral catheter within the range of 0–999 mL [50,51]. Reported limitations on its use are serious abdominal scars, uterine prolapse, and pregnancy [51,52] with false positives in cases of pelvic cysts [50] and at times hematomas.

Overall correlation of more recent models of Doppler planimetry the BME-150A (S & D Medicare Co., Seoul, Korea) and BladderScan BVI 3000 (Diagnostic Ultrasound Co., Bothell, WA) with catheterized bladder volumes (12 FG latex rubber urethral catheter) were 0.92 and 0.94, respectively, with a mean difference from true residual volume of 7.8 and 3.6 mL [53]. While both scanners were reported [53] to have good accuracy at low bladder volumes, like previous studies, exact sensitivities and accuracies for volumes under 100 mL have not been reported. Both types of bladder scanners do not have the other applications of conventional transabdominal, transvaginal, and transperineal ultrasound.

PVR Measurement by Other Methods

Not discussed here are those other possible methods of PVR assessment such as abdominal palpation and bimanual pelvic examination, which are imprecise. Radiology and radionucleotide scans have not gained favor as these techniques are more invasive, carry additional risks, and are also impractical in the settings outlined.

NORMAL AND ABNORMAL POSTVOID RESIDUALS AND URINARY RETENTION

PVRs in Asymptomatic Women

Using transvaginal ultrasound [46] within 60 seconds of micturition, the upper limit of normal PVR (95th centile) is 30 mL. In a study with measurement delayed to up to 10 minutes, an upper limit of normal of 100 mL has been quoted [54].

PVRs in Symptomatic Women

Using transvaginal ultrasound [31,47], the upper limit of normal (87th centile) is 30 mL. Other studies quote higher figures of 50 mL [55], 100 mL [56], and 150 mL [57]. All of the latter studies [55–57] used urethral catheterization with the postmicturitional delay (1) of up to 10 minutes or (2) untimed [55,57] in PVR measurement.

Prevalence of Immediate PVRs in Symptomatic Women

In a recent study of 1140 women presenting with symptoms of pelvic floor dysfunction [47], Haylen et al. showed that the prevalence of the different immediate (measured by transvaginal ultrasound within 60 seconds of voiding) PVRs were *0–10 mL, 76%; 11–30 mL, 5%; 31–50 mL, 15%; 51–100 mL, 8%; >100 mL, 6%; and >200 mL, 2%.*

Combining the data from studies [31] and [47], *an upper limit of normal for PVRs in symptomatic women of 30 mL*, is suggested.

Associations of Immediate PVRs in Symptomatic Women [47]

The prevalence of PVRs more than 30 mL was shown to increase significantly with *age* ($p < 0.001$) and *higher grades of prolapse* ($p < 0.001$). A PVR more than 30 mL is associated with a significantly higher risk of *recurrent urinary tract infections* (UTI—$p < 0.001$). There is an inverse relationship between a PVR more than 30 mL and the symptom of stress incontinence ($p = 0.018$) and the final diagnosis of USI ($p < 0.001$).

Acute Retention of Urine

This is defined as a generally (but certainly not always) painful, palpable, or percussable bladder when the patient is unable to pass any urine when the bladder is full [1].

Chronic Retention of Urine

This is defined as a nonpainful bladder, where there is a chronic high PVR. From Haylen et al.'s study [32], 200 mL might be a reasonable "cutoff" for chronic retention.

FINAL DIAGNOSIS OF VOIDING DYSFUNCTION

Diagnosis of VD

As stated in the introduction, VD is defined as an abnormally slow and/or incomplete micturition. This implies an abnormally slow urine flow rate and/or an abnormally high PVR. There should be confirmation by repeat measurement. Pressure–flow studies are indicated to evaluate the cause of any VD. Some possible causes are (1) *detrusor underactivity, (2) acontractile detrusor, and (3) bladder outflow obstruction* [1].

Prevalence of VD

Depending on definition, VD has a prevalence of 14% [58] to 39% [59] and more than 40% [60] the middle figure, making it either the third or fourth most common urodynamic diagnosis (after USI, pelvic organ prolapse, and possibly DO).

Criteria for Diagnosis of Voiding Dysfunction

The only validated criteria to date are (1) a urine flow rate under the 10th centile of the Liverpool nomogram and/or (2) an immediate PVR more than 30 mL. Alternate suggested criteria of a PVR more than 50 mL and a maximum urine flow rate under 15 mL/min require validation. More studies are required employing PVR criteria by urethral catheterization.

Associations of the Diagnosis of Voiding Dysfunction

The study of Haylen et al. [59] determined the following associations using the validated criteria in the earlier section. VD-1 uses the maximum urine flow rate; VD-2 uses the average urine flow rate.

- *Age*: There was a significant increase in the prevalence of VD with age (VD-1, VD-2: $p < 0.001$).
- *Parity*: There was a lesser but still significant increase with parity (VD-1, $p = 0.010$; VD-2, $p = 0.014$).
- *Presenting symptoms*: Symptoms of VD ($p < 0.001$) and prolapse ($p < 0.001$) were significantly linked to VD-1, VD-2 with the symptom ($p < 0.001$) and sign ($p < 0.001$) of stress incontinence significantly linked to NON VD-1, NON VD-2 (absence of VD).
- *Prior hysterectomy*: There was a significant relationship of VD to prior hysterectomy (VD-1, $p = 0.006$; VD-2, $p = 0.053$) and prior continence surgery (VD-1, $p = 0.008$; VD-2, $p = 0.010$) respectively. There was a greater increase in VD-1, VD-2 with vaginal hysterectomy compared with abdominal hysterectomy but the difference didn't reach significance.

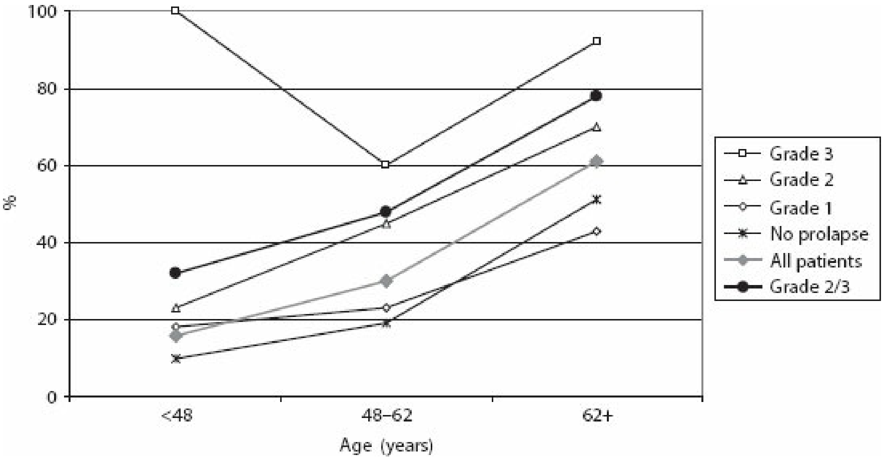

Figure 53.9 The relationship of VD-1 to age for (1) all patients, (2) patients with grade 0 prolapse (final diagnosis), (3) patients with grade 1 prolapse, (4) patients with grade 2 prolapse, and (5) patients with grade 3 prolapse.

- *Menopause*: Data initially showed that menopausal women on combined estrogen/progesterone therapy had significantly less VD than those not taking HRT. However, this effect was lost when age was taken into account.
- *Prolapse*: There is a significant relationship of VD to increasing grades of uterine prolapse, anterior vaginal wall (cystocoele), posterior vaginal wall (rectocele), and vaginal vault (enterocoele), respectively ($p < 0.001$ for VD-1 and VD-2 for all types of prolapse). Much of the relationship would be due to a PVR rather than a urine flow rate effect.
- *Retroverted uterus*: The relationship between the retroverted uterus and VD was nonsignificant ($p = 0.250$).

Figure 53.9 shows the relationship of VD-1 to age for (1) all patients, (2) patients with grade 0 prolapse (final diagnosis), (3) patients with grade 1 prolapse, (4) patients with grade 2 prolapse, and (5) patients with grade 3 (3–4) prolapse.

- *Recurrent UTIs*: There was no significant relationship between voiding difficulty (VD-1 [$p = 0.213$], VD-2 [$p = 0.213$]) and recurrent UTI. The strong relationship of PVRs and recurrent UTI noted earlier is not continued when urine flow rates are added to make the diagnosis of VD (urine flow rates appearing to have no significant association with recurrent UTI).

INDICATIONS TO SCREEN FOR VOIDING DYSFUNCTION

Uroflowmetry and PVR measurement should be regarded as an appropriate screening test for VD in all women with symptoms of pelvic floor dysfunction.

Abnormal urine flow studies in female patients are less common than in male patients. This is because in the male patient a high proportion of lower urinary tract problems are related to outflow obstruction. In the female, the incidence of outflow obstruction is low, whereas the incidence of incontinence and associated abnormalities of bladder behavior is high.

Urine flow studies and PVR are preliminary to cystometry that is necessary to define the urodynamic abnormality responsible for the symptom complex of frequency, nocturia, urgency, and urge incontinence. Anticholinergic medications will exacerbate any tendency toward urinary retention in patients with the combined diagnoses of DO and VD.

Urine flow studies and a PVR are an important preoperative investigation in women awaiting surgery USI. Assuming USI has been urodynamically proven, a normal urine flow rate and PVR reassure the surgeon that long-term VD is much less likely to follow the operation to cure the stress incontinence. Since effective surgery usually results in an increase in urethral resistance, in women with poor preoperative flow rates, incomplete emptying or even persistent failure to void may follow surgery [60]. Therefore, urine flow studies, with or without pressure flow studies, are to be recommended before surgery. An interrupted flow is associated with delayed postoperative voiding after suburethral tapes [61]. Voiding cystometry, as noted, is required to definitively diagnose bladder outflow obstruction.

Voiding problems in patients with neuropathic lower urinary tract dysfunction consists of three main types. Patients may experience incontinence as a result of bladder overactivity. The main problem may be the failure to empty the bladder because of a poorly sustained detrusor contraction. Detrusor sphincter dyssynergia may prevent an effective detrusor contraction from emptying the bladder with the consequent possible complications of recurrent infections or renal failure. Urine flow studies may suggest the origin of the problems experienced by this group of patients, although video–pressure–flow studies are desirable in almost every case.

ACKNOWLEDGMENT

The contribution of Dr. Paul Abrams to earlier chapters coauthored with the current author on uroflowmetry is acknowledged.

54 Pathophysiological Mechanisms of Chronic Pelvic Pain

Ursula Wesselmann

INTRODUCTION

Chronic pelvic pain syndromes belong to the category of visceral pain. Pelvic pain is a debilitating problem that can significantly impair the quality of life of a woman. Patients with chronic pelvic pain are usually evaluated and treated by gynecologists, urologists, gastroenterologists, and internists. Although these patients seek medical care because they are looking for help to alleviate their pelvic discomfort and pain, in clinical practice, much emphasis has been placed on finding a specific etiology and specific pathological markers for pelvic disease. These patients typically undergo many diagnostic tests and procedures. However, often the examination and workup remain unrevealing and no specific cause of the pain can be identified. In these cases, it is important to recognize not only that pain is a symptom of pelvic disease but also that the patient is suffering from a chronic pelvic pain syndrome, where "pain" is the prominent symptom of the chronic visceral pain syndrome.

This chapter will focus on the neurobiology of chronic nonmalignant pelvic pain, a chronic visceral pain syndrome. Knowledge of the neurophysiological characteristics of visceral pain will guide the physician in making a diagnosis of chronic pelvic pain and in differentiating it from the lump diagnosis of idiopathic pain [1]. A basic understanding of neurobiology is paramount to gain further insights into the mechanisms of the pelvic pain disorders and to develop effective clinical management strategies for patients presenting with these syndromes.

DEFINITIONS AND TAXONOMY OF CHRONIC PELVIC PAIN

Definitions are important if a body of reliable information, which will eventually lead to a better understanding of the pathophysiology of chronic pelvic pain, is to be built up in scientific literature [2]. At present, one of the major problems of research into chronic pelvic pain is the lack of agreed definitions, which would allow comparison between studies. On the other hand, the lack of understanding of the pathophysiological mechanisms of the pelvic pain syndromes makes it difficult to decide on criteria to define chronic pelvic pain conditions.

There is no generally accepted definition of chronic pelvic pain. Much debate over the classification of chronic pelvic pain has occurred, is ongoing, and will occur in the future. The International Association for the Study of Pain (IASP) initially defined chronic pelvic pain without obvious pathology as chronic or recurrent pelvic pain that apparently has a gynecological origin but for which no definitive lesion or cause is found [3]. However, this IASP definition for pelvic pain has not been widely used in the literature [4]. This definition implied the absence of pathology, which might not necessarily be the case, and it also excluded cases where pathology is present although not necessarily the cause of pain. In fact, the relationship of pain to the presence of pathology is often unclear in women with chronic pelvic pain.

The IASP has recently introduced an updated visceral pain taxonomy.*

The new IASP taxonomy defines chronic pelvic pain as chronic or persistent pain perceived in structures related to the pelvis of either men or women and explicitly recognizes that chronic pelvic pain is often associated with negative cognitive, behavioral, sexual, and emotional consequences as well as with symptoms suggestive of lower urinary tract, sexual, bowel, pelvic floor, or gynecological dysfunction.

Several medical societies have taken a lead in revising the taxonomy of chronic pelvic pain. The International Continence Society (ICS) has defined "pelvic pain syndrome" as the occurrence of persistent or recurrent episodic pelvic pain associated with symptoms suggestive of lower urinary tract, sexual, bowel, or gynecological dysfunction in the absence of proven infection or other obvious pathology in their 2002 consensus publication [5]. The ICS is currently preparing an updated consensus document regarding the ICS standards of terminology for symptoms, signs, diagnostic tests, and overall evaluation related to the nine domains of chronic pelvic pain in women and men: the lower urinary tract, female genital tract, male genital tract, gastrointestinal tract, musculoskeletal system, peripheral and central nervous system (CNS), psychological aspects, sexual dysfunction, and comorbidities.[†] The European Association of Urology has emphasized to move away from an organ-centered understanding of pain located in the pelvis to an understanding based on the mechanism of pain and integrating, as far as possible, psychological, social, and sexual dimensions of the problem [6]. In the gynecological literature, chronic pelvic pain is often referred to as pelvic pain in the same location for at least 6 months. The American College of Obstetricians and Gynecologists has proposed the following definition [7]: “Chronic pelvic pain is non-cyclic pelvic pain of 6 or more months’ duration that localizes to the anatomic pelvis, anterior abdominal wall at or below the umbilicus, the lumbosacral back, or the buttocks and is of sufficient severity to cause functional disability or lead to medical care. A lack of physical findings does not negate the significance of a patient’s pain, and normal examination results do not preclude the possibility of finding pelvic pathology.”

EPIDEMIOLOGY OF CHRONIC PELVIC PAIN

Chronic pelvic pain is a common condition. Epidemiological data from the United States showed that 14.7% of women in their reproductive years reported chronic pelvic pain [8]. Extrapolating to the total female population gave an estimated 9.2 million chronic pelvic pain sufferers in the United States alone. Analysis of a large primary care database from the United Kingdom demonstrated that the annual prevalence rate of chronic pelvic pain in women is 38/1000, which is comparable to the prevalence rate of asthma [9]. Diagnoses related to the urinary or gastrointestinal tracts were more common than gynecological causes [10]. Irritable bowel syndrome (IBS) accounts for 12% of primary care visits and 28% of gastroenterological practice [11]. While prevalence estimates vary widely, it has been suggested that somewhere between 450,000 [12] and one million people [13] in the United States suffer from interstitial cystitis/bladder pain syndrome (IC/BPS). Using the Nurses’ Health Study (NHS) I and II cohort as a study population, the prevalence of IC/BPS in NHS II was reported as 67/100,000 and in NHS I as 52/100,000 [14]. The Rand IC/BPS Epidemiology Study, a population-based symptom prevalence estimate study in adult females in the United States, concluded that there are 3.3–7.9 million women age 18 and older in the United States with IC/BPS; however, only 9.7% of these women reported being assigned a diagnosis of IC/BPS [15]. Female predominance of IC/BPS of about 5:1 or greater has been reported in previous studies, but a recent study showed that the prevalence of IC/BPS symptoms in men approaches that in women [16], raising the concern that this condition may be underdiagnosed and undertreated in men.

A recent WHO systematic review of the prevalence of chronic pelvic pain assessing the worldwide literature found that the rate for dysmenorrhea was 16.8%–81%, for dyspareunia 8%–21.8%, and for noncyclic pelvic pain 2.1%–24% [17]. Not surprisingly, the study found that there were few studies on chronic pelvic pain from less developed countries and the variation of rates of chronic pelvic pain worldwide was due to variable study quality. Importantly, wherever valid data were available, a high disease burden of pelvic pain was documented. Despite a high prevalence of pain, many women never had the condition diagnosed [18]. Populations at risk of having chronic pelvic pain seem to be women with a history of pelvic inflammatory disease, endometriosis, IC, IBS, obstetric history, previous abdominopelvic surgery, musculoskeletal disorders, and physical and sexual abuse [7].

INNERVATION OF THE PELVIS

Over the last 20 years, the basic neurobiology of the pelvis, despite the complexity of this region of the body, has come to be a reasonably well-developed discipline [19,20]. This section provides an overview of the innervation of the pelvis, which is a prerequisite to understanding the functional mechanisms that might play a role in the neuropathology of chronic pelvic pain. It is important to note that this summary attempts to derive as much information as possible from investigations involving humans although some generalizations are necessarily taken from animal studies, recognizing that much research in this field is in its infancy.

In general, the pelvis and the pelvic floor are innervated by both divisions of the autonomic nervous system (the sympathetic and parasympathetic), as well as by the somatic and sensory nervous systems.

In a discrete broad anatomic view, dual projections from the thoracolumbar and sacral segments of the spinal cord carry out this innervation, converging primarily into peripheral neuronal plexuses before distributing nerve fibers throughout the pelvis (Figure 54.1). Interactive neuronal pathways routing from higher origins in the brain through the spinal cord add to the complexity of neuronal regulation in the pelvis.

The nomenclature of the various plexuses, ganglia, and nerves in the pelvic cavity [21] is varied and sometimes confusing, presenting designations from both Nomina Anatomica (1977) and clinical usage [22]. In this chapter, the anatomic nomenclature is provided, and the clinical usage is given in brackets: superior hypogastric plexus (presacral nerve), hypogastric plexus (hypogastric nerve), inferior hypogastric plexus (pelvic plexus), and pelvic splanchnic nerve (pelvic nerve).

Within the pelvis, the inferior hypogastric plexus (pelvic plexus) is regarded as the major neuronal integrative center. This plexus is located retroperitoneally adjacent to each lateral aspect of the rectum, with interconnections between the left and right inferior hypogastric plexuses at the posterior aspect of the rectum. It innervates multiple pelvic organs, including the urinary bladder, proximal urethra, distal ureter, rectum, and internal anal sphincter, as well as genital and reproductive tract structures [23]. The anterior part of the inferior hypogastric plexus, associated with the distal extent of the hypogastric plexus (hypogastric nerve), is referred to as the paracervical ganglia in females [24].

The inferior hypogastric plexus receives sympathetic and parasympathetic input. Sympathetic nerves originate in the thoracolumbar segments of the spinal cord (T10–L2) and condense into the superior hypogastric plexus (presacral nerve) located just inferior to the aortic bifurcation. Preganglionic efferents originate largely in the intermediolateral cell column, whereas afferents have their cell bodies located in the dorsal root ganglia of these segments. Nerve fibers project from the superior hypogastric plexus as paired hypogastric plexuses (hypogastric nerves) and fuse distally before diverging bilaterally into branches destined for the inferior hypogastric plexuses. Additional sympathetic innervation to pelvic organs may involve preganglionic nerves, which synapse on postganglionic nerves originating in sympathetic chain ganglia; these postganglionic nerves join sacral nerves and course to their destinations via pelvic somatic neuronal pathways [25]. Parasympathetic preganglionic nerve efferents are thought to arise from cell bodies of the sacral parasympathetic nucleus located in the sacral spinal cord (S2–S4) and fuse as the pelvic splanchnic nerve (pelvic nerve) before entering the inferior hypogastric plexus [26]. Parasympathetic afferents have cell bodies located in the S2–S4 dorsal root ganglia and course also within the pelvic splanchnic nerve. In addition to its parasympathetic efferent and afferent component, the pelvic splanchnic nerve also receives postganglionic axons from the caudal sympathetic chain ganglia [27].

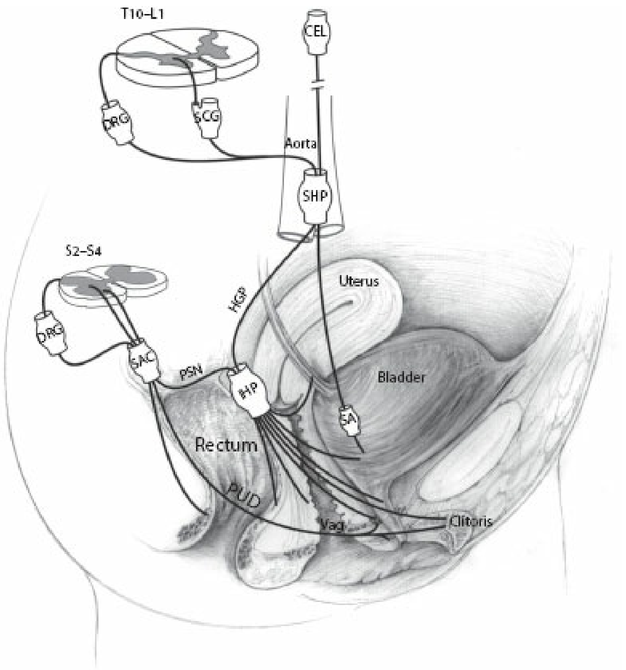

Figure 54.1 Innervation of the pelvic area in females. Although this diagram attempts to show the innervation in humans, much of the anatomic information is derived from animal data. *Abbreviations*: CEL, celiac plexus; DRG, dorsal root ganglion; HGP, hypogastric plexus; IHP, inferior hypogastric plexus; PSN, pelvic splanchnic nerve; PUD, pudendal nerve; SA, short adrenergic projections; SAC, sacral plexus; SCG, sympathetic chain ganglion; SHP, superior hypogastric plexus. (Reproduced from Wesselmann U et al., *Pain*, 73, 269, 1997. With permission of the International Association for the Study of Pain® (IASP). The figure may not be reproduced for any other purpose without permission.)

Somatic efferent and afferent innervation to the pelvis is generally understood to involve the sacral nerve roots (S2–S4) and their ramifications. Somatic efferents arise within Onuf's nucleus situated in the ventral horn of the S2–S4 spinal cord, and afferents reach the dorsal horn with their cell bodies in the dorsal root ganglia of these segments [28]. Central projections of somatic afferents overlap with pelvic nerve afferents within the spinal cord, which theoretically allows coordination of somatic and visceral motor activity [25]. The sacral nerve roots emerge from the spinal cord forming the sacral plexus, from which the pudendal nerve diverges (S2–S3). The pudendal nerve also receives postganglionic axons from the caudal sympathetic chain ganglia.

Nociception and pain arising from within the pelvis and pelvic floor involve diverse neuronal mechanisms. In general, sensations from the pelvic viscera are conveyed within the sacral afferent parasympathetic system, with a far lesser afferent supply from thoracolumbar sympathetic origins [29]. Receptive fields in the perineum are understood to be carried out primarily by sensory–motor discharges associated with pudendal nerve afferents [29,30]. While the interactions of sensory afferents are quite complex, likely possibilities by which these pathways exert effects on autonomic efferent function include mediatory effects on spinal cord reflexes and modulatory effects on efferent release in peripheral autonomic ganglia and in peripheral organs. These neural structures in the periphery comprise the first of numerous relays of sensory neurons, which transmit painful sensations from the abdominal/pelvic cavity to the brain.

Traditionally, it was thought that ascending pathways for visceral and other types of pain were mainly the spinothalamic and spinoreticular tracts. However, three previously undescribed pathways that carry visceral nociceptive information have been discovered: the dorsal column pathway, the spino(trigemino)-parabrachio-amygdaloid pathway, and the spinohypothalamic pathway [31]. Specifically, the dorsal column pathways play a key role in the processing of pelvic pain, and neurosurgeons have successfully used punctate midline myelotomy to relieve pelvic pain due to cancer [32]. In addition, descending facilitatory influences may contribute to the development of maintenance of hyperalgesia, thus contributing to the development of chronic pelvic pain [33].

DIFFERENCES BETWEEN VISCERAL AND SOMATIC PAIN

Persistent pain of visceral origin is a much greater clinical problem than that from the skin, but the overwhelming focus of experimental work on pain mechanisms relates to cutaneous sensation. Until relatively recently, it was often assumed that concepts derived from cutaneous studies could be transferred to the visceral domain. However, there are several reasons to believe that the neural mechanisms involved in pain and hyperalgesia of the skin are different from the mechanisms involved in painful sensations from the viscera [34,35]. In contrast to somatic pain, visceral pain cannot be evoked from all viscera and is not always linked to visceral tissue injury (see the "Visceral Nociceptors and Sensitization" section). In addition, visceral pain tends to be diffused and poorly localized, whereas somatic pain can be localized very precisely. This is due to the fact that the visceral innervation is not as dense as the somatic innervation and that there is an extensive divergence in the CNS. Further, visceral pain can be referred to other visceral structures and somatic structures of the same segmental level (see "Referred Visceral Pain Mechanisms").

Visceral Nociceptors and Sensitization

The existence of visceral nociceptors has been debated for a long time. This is partially due to the difficulty of defining and applying physiologically relevant noxious stimuli to the viscera. Research in animal models of visceral pain has shown that several types of sensory receptor exist in most internal organs and that different pain states are mediated by different neurophysiological mechanisms [36]. Acute, brief visceral pain appears to be triggered initially by the activation of high-threshold visceral afferents and by the high-frequency bursts that these stimuli evoke in intensity-coding afferent fibers, which are afferents with a range of responsiveness in the innocuous and noxious ranges. However, more prolonged forms of visceral stimulation, including those leading to hypoxia and inflammation of the tissue, result in sensitization of high-threshold receptors and the bringing into play of previously unresponsive afferent fibers (silent nociceptors; see below). This increased afferent activity enhances the excitability of central neurons and leads to the development of persistent pain states. In addition, a special class of C-fiber nociceptors—mechano-insensitive or "silent" nociceptors—has been found in nearly all tissues. They were first described in an animal model of experimental arthritis [37] and subsequently in animal models of visceral pain [38]. Silent afferents are activated only in the presence of tissue damage or inflammation. Following release of injury products, these previously silent receptors are activated by a wide range of thermal and mechanical stimuli and may also have a background discharge.

Referred Visceral Pain Mechanisms

There are two components of visceral pain, both of which were described more than 100 years ago [39]: "true visceral pain" (deep visceral pain arising from inside the body) and "referred visceral pain" (pain that is referred to segmentally related somatic and also other visceral structures). Secondary hyperalgesia usually develops at the referred site [40]. A number of explanations have been offered for the existence of referred pain [35]. An initial model for interpreting referred pain was based on the idea of viscerosomatic convergence occurring in primary afferent fibers, with multiple branches innervating both viscera and somatic structures. This hypothesis is unlikely since few branching axons have been found in animal studies. In addition, the hypothesis does not explain the time delay in the evolution of referred pain.

Another suggested mechanism for referred pain is that visceral and somatic primary neurons converge onto common spinal neurons. This is the convergence–projection theory. There is considerable experimental evidence for this hypothesis. It offers a ready explanation for the segmental nature of referred pain but does not address explicitly the issue of hyperalgesia in the referred zone. To interpret "referred pain with hyperalgesia," two main theories have been proposed, which are not mutually exclusive. The first is known as the convergence–facilitation theory. It proposes that the abnormal visceral input would produce an irritable focus in the relative spinal cord segment, thus facilitating messages from somatic structures. The second theory postulates that the visceral afferent barrage induces the activation of a reflex arc whose afferent branch is presented by visceral afferent fibers and the efferent branch by somatic efferents and sympathetic efferents toward the somatic structures (muscle, subcutis, and skin). The efferent impulses toward the periphery would then sensitize nociceptors in the parietal tissues of the referred area, thus resulting in the phenomenon of hyperalgesia.

When examining and treating a woman with chronic pelvic pain, it is important to consider both aspects of the pain syndrome (true and referred pain), including the pain deep in the pelvic cavity and pain referred to somatic structures (lower back and legs) and other visceral organs. Considering the concept of referred visceral pain will allow the physician to look at the global picture of visceral dysfunction, rather than "chasing" one aspect of the visceral pain syndrome out of context.

COMORBIDITIES AND PELVIC PAIN

Careful clinical history and examination show that patients with pelvic pain often suffer from "more than one pain." These clinical observations are supported by epidemiological studies. Data from the Interstitial Cystitis Data Base Study [41] show that 93.6% of the patients enrolled with a diagnosis of IC reported having some pain in some part of their body. Of the patients having pain, 80.4%, 73.8%, 65.7%, and 51.5% reported having pain in their lower abdomen, urethra, lower back, and vaginal area, respectively. There is substantial overlap observed between chronic pelvic pain and other abdominal and urogenital symptoms [18,42,43]. These observations could be explained pathophysiologically by referred visceral pain mechanisms to other visceral and somatic areas with overlapping spinal cord projections. In addition, there is increasing clinical and epidemiological evidence of the co-occurrence of chronic pelvic pain conditions with chronic pain syndromes in other "nonpelvic" body areas (e.g., fibromyalgia), raising the question of systemic alterations of pain modulatory mechanisms in this patient population [44].

These epidemiological studies to assess comorbidities of chronic pelvic pain conditions require validated case definitions to identify the comorbid conditions in large populations, and the results of these studies depend on the range of comorbidities that are screened for. For example, vulvodynia in women is a pain comorbidity, which has only more recently been included in such efforts, probably because this body area is considered taboo [45–47].

Patients with IC/BPS typically present with fibromyalgia, chronic fatigue syndrome, IBS, temporomandibular disorder, migraine, chronic pelvic pain, vulvodynia, low back pain, sicca syndrome, allergies, asthma, depression, and anxiety [48]. Several studies have recently also confirmed the coexistence of endometriosis and IC/BPS, ranging from 16% to 78% [49]. Epidemiological studies have demonstrated that the odds ratios for IC/BPS increases with increasing numbers of antecedent nonbladder syndromes [48,50]. The distribution of nonbladder syndrome types was skewed, with allergy overrepresented in those with few nonbladder syndromes, and the classic functional somatic syndromes of fibromyalgia, chronic fatigue syndrome, and IBS were overrepresented in those with many nonbladder syndromes [50]. A common theme to this group of comorbid disorders could be related to the autonomic nervous system, and indeed a recent study [51] identified a high level of autonomic dysfunction in subjects with IC/BPS including poor sleep function, Raynaud's-like symptoms, and orthostatic symptoms.

Thus, research efforts to elucidate the pathophysiological mechanisms of pelvic pain have recently shifted from an organ-based approach to a more global approach (http://www3.niddk.nih.gov/fund/other/ http://www.mappnetwork.org/).

PHARMACOLOGICAL ASPECTS

Despite the fact that it is a very common chronic pain syndrome, very little is known about effective pharmacological treatment for chronic pelvic pain [52–55]. Pharmacological pain management is empirical only. Often, drugs are used to alleviate chronic pelvic pain, which have shown efficacy for the treatment of chronic neuropathic pain states [54]. Very few drugs have been specifically approved for the treatment of chronic pelvic pain syndromes. An example is Elmiron (pentosan polysulfate sodium), which is indicated for the relief of bladder pain or discomfort associated with IC/BPS. Controlled clinical trials are desperately needed to design improved pharmacological treatment strategies.

The principal guidelines for pharmacological pain management for chronic pelvic pain are similar to the pharmacological treatment of other chronic pain states. Although clinical trials and case reports on the pharmacological management of chronic pain syndromes provide general guidelines as to which drug to choose, currently we have no method to predict which drug is most likely to alleviate pain in a given patient. The goal of pharmacotherapy is to find a medication that provides significant pain relief with minimal side effects. It is important that the patient understands the limitations of this “trial-and-error” method of prescribing drugs. Adequate trials should be performed for each drug prescribed and only one drug should be titrated at a time, otherwise it is not possible to assess the effects of a certain drug on pain scores. The starting dose should always be the smallest available and titration should occur at frequent intervals, guided by pain scores, and side effects. This requires frequent contact between the patient and the pain clinic during the titration period. It is important for the patient and the physician to understand that some side effects actually improve as the patient continues to take the drug for several weeks. If these side effects are not intolerable, the patient should be guided through this period.

Since epidemiological data have confirmed the widespread existence of chronic pelvic pain in the female population in the last 20 years, there is growing interest in the pharmaceutical industry to expand basic science and clinical research efforts for this underserved patient population. Realizing the sometimes marked differences in the expression and function of receptors in visceral and somatic pathways has led to new pharmacological research explorations of both new and previously overlooked potential therapeutic targets [55,56], which might provide new avenues for treating chronic pelvic pain in the future.

Several receptor targets have been identified in the pelvis and urogenital tract, which might play a role in pelvic pain [56]. The mammalian transient receptor potential channels play a role in sensing mechanisms throughout the body, including the pelvis. Pharmacological interventions targeting these ion channels might provide a new opportunity for painful bladder syndrome and other chronic pelvic pain syndromes [55,57–61]. Prostaglandins are synthesized in response to tissue injury by cyclooxygenase. They sensitize sensory fibers to mechanical and thermal stimuli and contribute to spinal processing of visceral pain [62]. Cytokines and other neuroactive substances associated with inflammation also have a clear role in visceral inflammatory pain states. *N*-methyl-d-aspartate (NMDA) receptors are expressed in primary afferents and in dorsal horn neurons. Intrathecal application of NMDA and non-NMDA receptor antagonists significantly attenuate visceral hypersensitivity in behavioral models, and spinal application of NMDA agonists increases the magnitude and duration of visceral pain responses [63,64]. ATP is released from all tissue types when there is tissue damage. In visceral tissue, ATP binds ionotropic purinergic (P2X) receptors. P2X3 receptors are specific for nociceptors and P2X receptor antagonists attenuate colonic afferent activity [65–67]. ATP, released from the bladder urothelium, binds P2X3 receptors on bladder afferents increasing bladder contraction and micturition [68,69]. This also increases bladder afferent activity resulting in pain. P2X3 knockout mice have urinary bladder hyporeflexia with increased voiding volume and decreased voiding frequency and decreased inflammatory pain [70,71]. The corticotropin-releasing factor (CRF) receptor is involved in the stress response, activating the hypothalamic–pituitary–adrenal (HPA) and sympathoadrenal axes. Women with chronic pelvic pain demonstrate HPA axis alterations similar to patients with other stress-related bodily disorders [72]. Enhanced pelvic responses to stressors have been demonstrated in CRF-overexpressing mice [73]. Opioids constitute a major class of analgesics to treat visceral pain. Nociceptin–orphanin receptor agonists have been used in preclinical models of pelvic pain with promising potential for therapeutic effects. This antihyperalgesic effect does not involve a CNS site of action [74]. In summary, modulation of visceral nociceptive pathways can occur at peripheral, spinal, and supraspinal sites. There is a concerted effort underway to develop target-specific visceral analgesics for the treatment of chronic pelvic pain [75]. However, based on the recognition that chronic pelvic is a heterogeneous group of conditions and learning from previously failed clinical trials, the discovery of a single target for the treatment of chronic pelvic pain is unlikely. A key issue for the success of future clinical trials will be improved patient phenotyping to identify subgroups of patients with chronic pelvic pain, based on aspects such as clinical symptoms, quantitative sensory testing parameters, biomarkers, and comorbid conditions.

CLINICAL IMPLICATIONS

Treating patients with chronic pelvic pain remains a significant clinical challenge. Given the many comorbidities observed in this patient population, it will be important to identify which patients will be at risk to develop other chronic pain syndromes and to design strategies for early intervention. As the pathophysiological mechanisms of visceral pain explored in basic science research provide an explanation for some of the clinical phenomena observed in patients, additional, revived, and new concepts of chronic pelvic pain have emerged:

1. A spectrum of different insults might lead to chronic pelvic pain.
2. Different underlying pathogenic pain mechanisms may require different pain treatment strategies for patients presenting with pelvic pain.
3. Multiple different pathogenic pain mechanisms may coexist in the same patient presenting with chronic pelvic pain, requiring several different pain treatment strategies (perhaps concomitantly) to treat visceral pain successfully [53].

These are the very exciting times for the field of pelvic pain, since pelvic nociceptive pathways are being identified and pharmacological compounds are being discovered to modulate visceral nociceptive pathways. Clinical guidelines have been developed in several countries over the last 15 years proposing an integrated approach to chronic pelvic pain syndromes by a multidisciplinary team of health-care providers [6,56,76,77]. The need for a multidisciplinary team approach to pelvic pain syndromes will require changes in the health-care system to allow a coordinated involvement of multiple teams, beyond the historic boundaries of medical subspecialties and of primary and secondary care. This has recently been address in the British Pain Society's pelvic pain patient pathway map [78] and in the pain report of the Institute of Medicine in the United States, issued at the request of the Congress as part of President Obama's health reform legislation [79].

55 Bladder Pain Syndrome/Interstitial Cystitis

Amina Douglas, Matthew Parsons, and Philip Toozs-Hobson

INTRODUCTION

Bladder pain syndrome/interstitial cystitis (BPS/IC) is a debilitating, chronic disease that has a negative impact on patient's quality of life. The etiology of the disease is unknown and it remains a diagnosis of exclusion. It is characterized by pelvic, bladder, and urethral pain associated with irritative voiding symptoms including urinary frequency, urgency, and nocturia.

The nomenclature and definition of the disease has changed over the years. The symptomatology of the BPS was first described in 1808 by Philip Physick, an American physician from Philadelphia. He described a disease of bladder pain not associated with the finding of bladder stones. In 1915, Guy Hunner reported Hunner's ulcers. On cystoscopy, he described seeing scarred-looking areas surrounded by one or more areas of hyperemia that bleed on touch in the bladders of women with a long history of bladder symptoms for which no cause had been found [15]. The term "interstitial cystitis" was used to describe patients with bladder pain and typical cystoscopic findings such as glomerulations and Hunner's ulcers. In 1987, the National Institute of Diabetes and Digestive and Kidney Disease (NIDDK) published criteria for research purposes to define IC [11]. These criteria have little clinical application. They are restrictive and when applied clinically can lead to missed diagnoses of IC in many patients. The International Continence Society later developed the term "painful bladder syndrome" to describe the clinical condition. Its definition did not include abnormal cystoscopic findings [2]. The condition was renamed "bladder pain syndrome" in 2008 by the European Society for the Study of Interstitial Cystitis. More recently, the International Consultation on Incontinence [14] revised the definition of BPS. It now defines the condition as chronic pelvic pain, pressure, or discomfort perceived to be related to the urinary bladder accompanied by at least one other urinary symptom: persistent urgency or urinary frequency.

INCIDENCE

Women between the ages of 40 and 60 years are the most commonly affected. The condition occurs in both females and males but has a 9:1 female predominance. It occurs most frequently in Caucasians. The reported prevalence of BPS/IC varies between populations and has changed with time. Berry et al. [5] reported the prevalence of BPS/IC to between 2.7% and 6.5% in American women. Nickel [24] reported prevalence ranging from 8 out of 100,000 in the Netherlands to 500 out of 100,000 in some parts of the United States. This variation is in part due to the lack of standardized diagnostic criteria for BPS/IC and the changes in the definition of the disease over time.

ETIOLOGY

Despite being first described over 100 years ago, the cause of BPS/IC remains unknown. The disease process is probably multifactorial with patients having one or more causative factors. Over the years, investigators have demonstrated specific pathologies that may contribute to the symptoms of the disease. As a result, several theories of the pathogenesis have been postulated and some are listed in the following texts.

Infection

Even when it was first described, infection was suspected as the cause of BPS/IC. BPS/IC has many hallmark symptoms of bacterial cystitis; however, urine analyses and urine culture demonstrate no evidence of infection [22]. It has been postulated that an initial bacterial infection may have been the cause of bladder damage causing the lasting symptoms of BPS/IC [9,54]. However, to date, no consistent organism has been isolated in the urine or bladder biopsy specimens of patients with BPS/IC.

Indeed, the NIDDK criteria and the International Consultation on Incontinence (ICI) [14] require infection to be excluded before a diagnosis of BPS/IC can be made.

Autoimmune Disorder

Studies have shown an association between BPS/IC and autoimmune disorders including Sjogren's syndrome [51], systemic lupus erythematosus [3], and also allergies. The evidence for this, however, has not always been consistent.

Mast Cells

Mast cells are multifunctional immune cells. They contain numerous vasoactive and proinflammatory substances such as histamine, prostaglandins, and tryptase. Many of these substances are contained within cytoplasmic granules. Mast cells are found within the bladder mucosa and detrusor muscle. Neuroimmune interaction involving mast cells in the bladder may explain the neuropathic pain seen in BPS/IC. Mast cells have a close spatial relation with nerves in the bladder. Activation of mast cells results in the release of mast cell granules. The release of inflammatory mediators from these granules results in neuronal sensitization, sensory nerve upregulation, neuropathic pain, and the release of neurotransmitters that further simulate mast cells. This vicious circle contributes to the chronic and painful symptoms associated with BPS/IC [46]. The increased number of mast cells and activation has been shown in some patients with BPS/IC [47,49]. However, increased numbers of mast cells have also been reported in patients with other diseases including endometriosis and irritable bowel syndrome [4,30]. The role of mast cells in the etiology of BPS/IC is still not clearly understood.

Vascular Abnormalities and Hypoxia

Abnormality in the bladder vasculature resulting in relative ischemia of the bladder has been suggested to be partly responsible for some of the symptoms of BPS/IC [42,44].

Dysfunctional Bladder Epithelium and Potassium Cycling

Parsons et al. [32] suggested that dysfunctional bladder epithelium resulting in abnormal (increased) bladder epithelial permeability is the cause of the symptoms of BPS/IC. In a healthy bladder, the transitional epithelium is relatively impermeable. A protective layer composed of glycosaminoglycans (GAGs) lines the urothelium. The GAG layer acts as a barrier rending the bladder epithelium impermeable to urinary solutes, which may be toxic to the bladder. Damage to this protective layer results in toxic solutes in particular potassium diffusing into the bladder, affecting the sensory nerves and injuring tissue. The theory of potassium cycling, developed from this, suggests that potassium diffuses into the bladder interstitium once the epithelium permeability is impaired. It depolarizes sensory nerve endings and muscles and leads to tissue injury. Parsons suggests that this pathophysiological process is responsible for the generation of symptoms of urgency and pain in patients with BPS/IC.

Parsons developed the potassium sensitivity test (PST) as an office-based diagnostic tool for BPS/IC in patients in whom the diagnosis was not clear on history alone. The test involved instillation of two separate solutions, sterile water and potassium chloride in the bladder of patients suspected of having BPS/IC. The PST is positive when a patient reacts preferentially to potassium versus water. PST tests for both the presence of bladder epithelial dysfunction and the hypothesis of potassium cycling. A patient with no symptoms who has a normal bladder epithelium would not be experiencing any symptoms when potassium is instilled, while a patient with impaired bladder epithelium will experience symptoms with potassium instillation [32]. The usefulness of PST has been debated and it is thought to be of low specificity and of questionable value in routine clinical practice [12].

CLINICAL FEATURES

Patients with BPS/IC typically complain of chronic pelvic pain. This may be associated with daytime as well as nighttime frequency, nocturia, and urgency. These symptoms occur in the absence of urinary tract infection. It is often said that suprapubic pain aggravated by bladder filling and relieved by voiding is classic of BPS/IC. However, this is not always the case. In some patients, the pain may be in the perineum, urethra, or vagina. The nature of the pain is also variable. It may be experienced as a sharp pain, as pressure, or as burning. The disease may be progressive but often presents in cycles of flares and remission. Flares may be provoked by a number of factors including sexual activity, hormonal fluctuations, and physical and emotional stress [31,37].

BPS/IC is a debilitating disease. It impairs quality of life and causes depression, sleep deprivation, and difficulties with sexual intercourse [25,50]. A close association has been reported between BPS/IC and other chronic conditions including irritable bowel syndrome, chronic fatigue syndrome, and fibromyalgia [1].

INVESTIGATION AND ASSESSMENT

BPS/IC remains a diagnosis of exclusion. Investigations performed are done to exclude other diseases that may account for the patient’s symptoms and assess the severity of BPS/IC.

A history should be taken to establish the duration of symptoms and elucidate if there are other associated symptoms that would suggest an alternative diagnosis. A previous history of bladder disease, pelvic surgery, or other medical illnesses including irritable bowel syndrome and autoimmune disease should also be established.

Pelvic Examination

Pelvic examination is often unhelpful in making the diagnosis of BPS/IC. The abdomen should be palpated to assess for bladder tenderness. Examination is often more helpful in excluding other conditions that can cause similar symptoms. Women who complain of vaginal or vulval pain should be examined with pain mapping of the vulval region and for tenderness in the urethra, bladder, and levator and adductor muscles of the pelvic floor [53].

Urine Studies

Urine culture is essential to exclude simple urinary tract infection as well as atypical infections caused by *Ureaplasma urealyticum*, *Mycoplasma hominis*, or *Chlamydia trachomatis*.

Cytology is recommended if hematuria is present or if there are risk factors for bladder cancer (smoking, age, family history, and occupational exposure to certain industrial chemicals such as aromatic amines). If there is sterile pyuria, culture for tuberculosis and fastidious organisms should be performed.

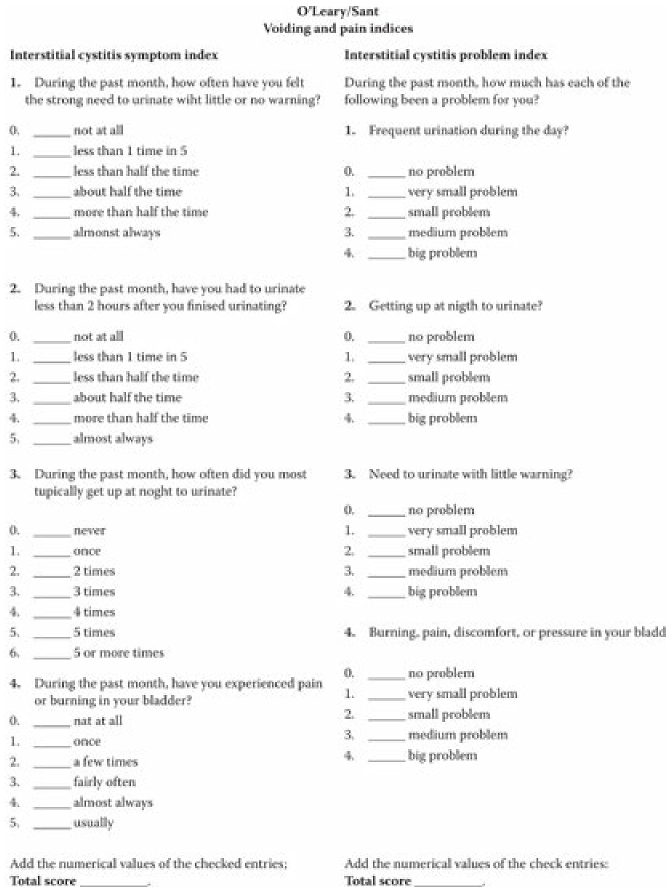
Questionnaires and Symptom Scales

Questionnaires are widely used for the evaluation of the severity of the patient’s symptoms and also to assess their progress. The ideal questionnaire is one which is brief and reliably distinguishes BPS/IC from other causes of the patient’s symptoms. There are three IC symptom questionnaires:

1. The University of Wisconsin IC scale
2. O’Leary–Sant symptom and problem index
3. Pelvic pain and urgency/frequency patient symptom scale (PUF questionnaire)

The University of Wisconsin IC scale has not been validated for use in identifying and diagnosing IC. It does, however, address some quality of life issues unlike the other two questionnaires and could therefore prove to be clinically useful.

The O’Leary–Sant and PUF questionnaires (Figures 55.1 and 55.2) are validated questionnaires completed by patients and are used to help identify patients with BPS/IC from those without the disorder. The O’Leary–Sant questionnaire was developed by focus groups and validated by administration to patients with IC and asymptomatic controls [18,28]. The O’Leary–Sant questionnaire focuses questions on symptoms of urgency and frequency and bladder-related pain. It does not, however, address the relationship between these symptoms and sexual activity or more general issues.



O'Leary/Sant
Voiding and pain indices

Interstitial cystitis symptom index

1. During the past month, how often have you felt the strong need to urinate wiht little or no warning?

0. ______ not at all
1. ______ less than 1 time in 5
2. ______ less than half the time
3. ______ about half the time
4. ______ more than half the time
5. ______ almonst always

2. During the past month, have you had to urinate less than 2 hours after you finised urinating?

0. ______ not at all
1. ______ less than 1 time in 5
2. ______ less than half the time
3. ______ about half the time
4. ______ more than half the time
5. ______ almost always

3. During the past month, how often did you most tupically get up at noght to urinate?

0. ______ never
1. ______ once
2. ______ 2 times
3. ______ 3 times
4. ______ 4 times
5. ______ 5 times
6. ______ 5 or more times

4. During the past month, have you experienced pain or burning in your bladder?

0. ______ nat at all
1. ______ once
2. ______ a few times
3. ______ fairly often
4. ______ almost always
5. ______ usually

Add the numerical values of the checked entries;
Total score __________.

Interstitial cystitis problem index

During the past month, how much has each of the following been a problem for you?

1. Frequent urination during the day?

0. ______ no problem
1. ______ very small problem
2. ______ small problem
3. ______ medium problem
4. ______ big problem

2. Getting up at nigth to urinate?

0. ______ no problem
1. ______ very small problem
2. ______ small problem
3. ______ medium problem
4. ______ big problem

3. Need to urinate with little warning?

0. ______ no problem
1. ______ very small problem
2. ______ small problem
3. ______ medium problem
4. ______ big problem

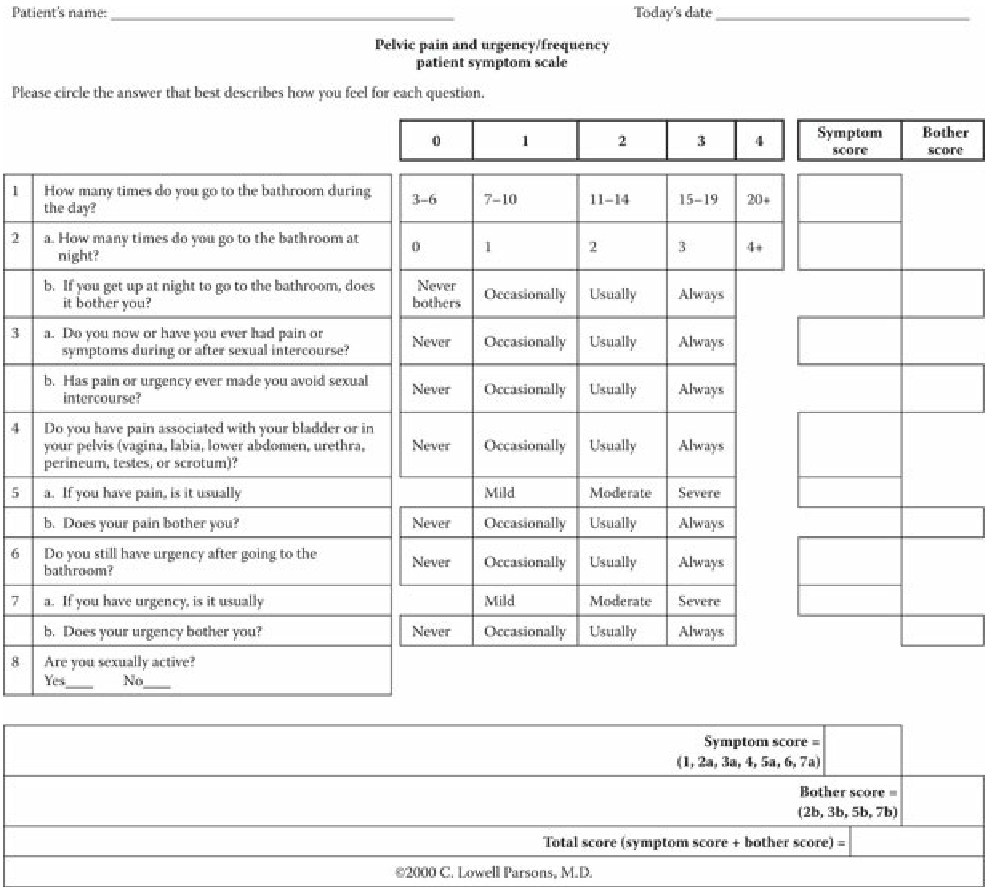
4. Burning, pain, discomfort, or pressure in your bladd

0. ______ no problem
1. ______ very small problem
2. ______ small problem
3. ______ medium problem
4. ______ big problem

Add the numerical values of the check entries:
Total score __________.

Figure 55.1 O'Leary–Sant questionnaire.

The PUF questionnaire was published more recently and was studied in large population of both gynecologic and urological patients [35]. The PUF questionnaire includes questions that address the wide range of symptoms that patients with this disorder may experience. It includes questions on frequency, urgency, and pain in both the bladder and pelvis and tries to assess the amount of bother caused to the patient by these symptoms. A study by Ref. [35], which utilized the PUF questionnaire, concluded that 23% of American females were affected by IC, and this has made many experts wary of its use.



Patient's name: ______________________ Today's date ______________

Pelvic pain and urgency/frequency
patient symptom scale

Please circle the answer that best describes how you feel for each question.

		0	1	2	3	4	Symptom score	Bother score
1	How many times do you go to the bathroom during the day?	3–6	7–10	11–14	15–19	20+		
2	a. How many times do you go to the bathroom at night?	0	1	2	3	4+		
	b. If you get up at night to go to the bathroom, does it bother you?	Never bothers	Occasionally	Usually	Always			
3	a. Do you now or have you ever had pain or symptoms during or after sexual intercourse?	Never	Occasionally	Usually	Always			
	b. Has pain or urgency ever made you avoid sexual intercourse?	Never	Occasionally	Usually	Always			
4	Do you have pain associated with your bladder or in your pelvis (vagina, labia, lower abdomen, urethra, perineum, testes, or scrotum)?	Never	Occasionally	Usually	Always			
5	a. If you have pain, is it usually		Mild	Moderate	Severe			
	b. Does your pain bother you?	Never	Occasionally	Usually	Always			
6	Do you still have urgency after going to the bathroom?	Never	Occasionally	Usually	Always			
7	a. If you have urgency, is it usually		Mild	Moderate	Severe			
	b. Does your urgency bother you?	Never	Occasionally	Usually	Always			
8	Are you sexually active? Yes____ No____

Figure 55.2 Pelvic pain and urgency/frequency scale.

As yet, none of the questionnaires has been shown to be of value in terms of diagnosis [21]. They are used to screen patients with urinary tract symptoms to identify those who should be further examined for IC or to follow those who have already been diagnosed [17]. The questionnaires help evaluate patient's response to treatment and follow the course of the disorder.

Voiding Diary

The voiding diary (Figure 55.3) is a useful tool in the investigation of lower urinary tract symptoms. Fluid intake and output is recorded by the patient in the diary for initial evaluation. Voiding diaries help to assess the degree of frequency, nocturia, and volumes voided at each episode. They are also useful in the identification of polydipsia and polyuria, which cause urinary frequency. They help to ascertain the highest functional capacity, which is usually the maximum voided amount and patient sensation at each void. Patients with BPS/IC have lower volumes at time of sensation to void and lower functional capacity than those without the condition [16]. It is therefore usual to see women with BPS/IC having frequent voids of small volume.

Urodynamics

Urodynamics has no role in the diagnosis of BPS/IC as there are no existing urodynamic findings specific for BPS/IC. Its use is to exclude confusable diseases such as detrusor overactivity or obstructed voiding that may be the cause of the patient's symptoms. It is not performed routinely if the diagnosis is certain from the history but is reserved for select cases where the diagnosis is uncertain.

Cystoscopy

Cystoscopy and biopsy is used to exclude diagnosis of bladder cancer or urethral diverticulum in those with risk factors or suggestive symptoms.

It is also used for the identification of Hunner's ulcers (Figure 55.4). The presence of Hunner's ulcers was previously thought to be pathognomonic of what was defined as IC. Cystoscopy with hydrodistension during general or regional anesthesia is required to substantiate the occurrence of Hunner's ulcers. During rigid cystoscopy, the bladder is filled at a pressure of 80 cmH_2O above the patient's bladder until the flow ceases and maximum capacity is reached. The bladder is emptied and then refilled to approximately 20%–50% of capacity inspecting for lesions and hemorrhages (Figure 55.5) that are evident on the second filling. Hunner's ulcers typically involve the dome and posterior and lateral walls of the bladder and spare the trigone [27]. Biopsy may be necessary to confirm that it is such a lesion. Hunner's ulcers are rare findings. Glomerulations are the most common cystoscopic abnormality following hydrodistension in patients with BPS/IC [20,26]. Glomerulations are areas of submucosal bleeding. They are not specific to BPS/IC and as such their identification at time of cystoscopy is not diagnostic of BPS/IC. Glomerulations have been identified in the bladders of patients without bladder disease or bladder pain [10,55].

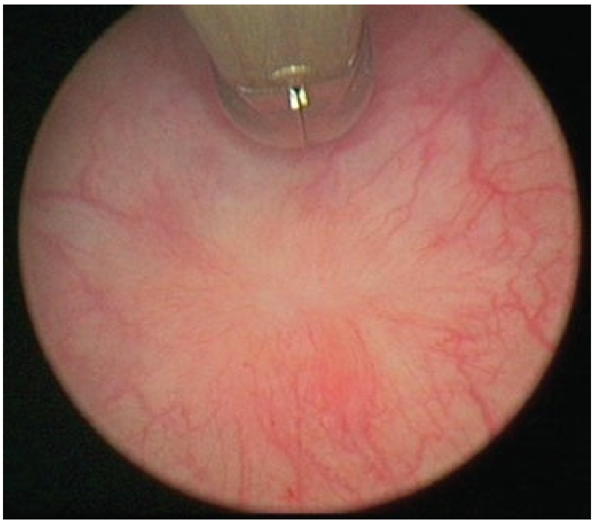

Figure 55.4 Cystoscopic appearance of Hunner’s ulcer.

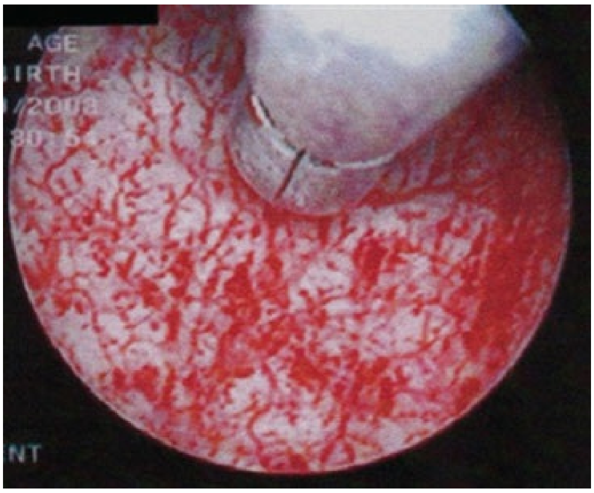

Figure 55.5 Cystoscopy showing abnormal petechial hemorrhages in investigation of bladder pain.

MANAGEMENT

The aim of treatment is to achieve symptom control by addressing the underlying pathophysiological process. This is often difficult to achieve as the etiology of the disease is not well understood. The available treatment strategies can be classified into conservative, bladder instillation therapy, medical, and surgical. The scientific evidence for most of these treatments is weak or lacking.

Treatment strategies should proceed using more conservative therapies first; surgical treatments are generally reserved for intractable disease that has not responded to other treatment modalities.

Patient education is an important initial step in disease management. Patients should be educated about the disease and informed about current knowledge of BPS/IC and available treatment modalities. They should be made aware of the fact that no single treatment is curative and that symptom control may require a trial of multiple therapeutic options (including combination therapy) before it is achieved [43]. There are several online databases, health magazines, and educational videos available that provide information about BPS/IC that patients should be encouraged to access. The Interstitial Cystitis Association (ICA) and its affiliated international organizations are also an important resource that patients should be made aware of.

Conservative

Behavioral Modification

Patients with BPS/IC typically have frequent small voids. For selected group of highly motivated patients in whom the predominant complaint is urinary frequency, behavioral modification in the form of timed voiding, controlled fluid intake, keeping a bladder diary, pelvic floor muscle training, and bladder retraining may be beneficial. Chaiken et al. [6] reported reduced daytime frequency and increased functional capacity in patients who underwent short-term behavioral therapy.

Dietary Manipulation

Avoidance of certain foods appears in some patients to improve their symptoms. Although the clinical data are lacking many, patients have reported benefit from dietary alteration. Caffeinated or alcoholic drinks, spicy foods, and citrus fruits have all been reported to aggravate symptoms. The ICA produced the IC food list, which lists foods reported by patients to trigger bladder symptoms and those that are less bothersome to the bladder. It is available to download at the ICA website, www.ichelp.org/ICFoodList.

Stress Management

Stress has been shown to exacerbate BPS/IC symptoms [45]. Stress management is an essential part of treatment where stress is contributory. Commonly used techniques include yoga, meditation, and guided imagery. Where possible, the stress-inducing factor should be removed or reduced as much as possible.

Cystoscopy and Hydrodistension under Anesthesia

This is considered to be both diagnostic and therapeutic. Cystoscopy is diagnostic as it allows identification of bladder pathology such as bladder tumors or Hunner's ulcers. If present, Hunner's ulcers can be treated. Hydrodistension enables the bladder capacity to be determined. It is also thought to be therapeutic as it has been shown to provide symptomatic relief in some patients. Its effects are, however, only short lasting and so it is not considered first-line treatment [7,29].

Oral Therapy

Amitriptyline

This is a tricyclic antidepressant commonly used for pain management. Its analgesic effect is thought to be due to its ability to inhibit serotonin and noradrenaline reuptake in the central nervous system. It also has anticholinergic effects and appears to stabilize mast cells. It can be used in doses up to 100 mg per day and has been shown to be a beneficial treatment for pain in patients with BPS/IC. A double-blind placebo-controlled trial by Ref. [52] reported greater than 30% decrease in O'Leary–Sant symptom score in the patients treated with amitriptyline compared to 13% reduction in symptoms in the placebo group. Side effects including fatigue, weight gain, and dry mouth are a common reason for patients to stop treatment.

Gabapentin

GABA agonist is usually used in the treatment of seizures. It has also been found to be useful in the treatment of neuropathic pain and can be used as an analgesic in patients with BPS/IC. The most common reported side effect is fatigue.

Antihistamines

Cimetidine, an H_2-receptor antagonist, has been found to be effective in the treatment of BPS/IC [48]. Its mechanism of action, however, remains unknown.

Pentosan Polysulfate Sodium

Pentosan polysulfate sodium (PPS) is a synthetic highly sulfated polysaccharide. Its structure is similar to heparin sulfate, one of the GAGs in the bladder. When taken orally, it appears that 2%–6% of it is excreted unchanged in the urine. Its mechanism of action is thought to be by replacing the deficient GAGs in the bladder, thus decreasing altered bladder permeability. It is available in oral formulation and given at dosage of 100 mg three times daily. In a randomized, prospective, double-blind, placebo-controlled trial conducted by [34], 32% of 148 patients treated with PPS reported significant improvement in symptoms, compared with 16% in the placebo group ($p = 0.01$). PPS remains the medication of choice for most patients. Patients should be advised that it may take up to 6–9 months for the full effect of the drug to be attained.

Intravesical Treatments

Intravesical treatments involve direct administration of the drug into the bladder. They are usually used alone as second-line treatment or in conjunction with oral therapy and other forms of conservative management. The available intravesical drug treatments include the following:

Dimethyl Sulfoxide

Dimethyl sulfoxide (DMSO) was first synthesized as a by-product of the wood industry. It was found to have anti-inflammatory and analgesic properties. It is the most widely used intravesical drug treatment for BPS/IC. Its mechanism of action is not clearly understood; however, it has been shown to be an effective treatment of BPS/IC. Objective improvement was noted in 93% of patients with cystoscopy-positive IC treated with DMSO versus 35% in the placebo group [39]. A common side effect of the drug is garlic-like odor to the breath. Treatment is usually performed on a weekly basis for 6–8 weeks after which treatment is discontinued until symptoms recur.

Heparin

It is thought that instillation with heparin, a GAG, may also afford protection to the urothelium by replacing the GAG layer. It has not been associated with coagulation abnormalities when administered intravesically and has been reported to be useful in the treatment of IC. In a study by Parsons et al., 56% of patients reported improvements in their symptoms within 3 months of treatment [36].

Bacillus Calmette–Guerin

Bacillus Calmette–Guerin (BCG) is an attenuated strain of *Mycobacterium bovis*. Its precise mechanism of action is unknown. Studies have reported it to be effective in the symptomatic management of BPS/IC. Peters et al. [40] reported improvement in symptoms in 60% of patients treated with BCG compared to 27% in the placebo group. A larger randomized trial, however, did not show a significant response in patients treated with BCG compared to those treated with DMSO [38]. The clinical benefit of this treatment remains unclear.

Botulinum Toxin A

This is a potent neurotoxin derived from the bacterium *Clostridium botulinum*. There is emerging evidence that suggests botulinum toxin is beneficial in the treatment of BPS/IC [41]. However, many of these studies are small with short-term follow-up only. The treatment regime and dose of botulinum toxin has also not been standardized. Until further evidence from larger trials become available, botulinum toxin is not recommended for use outside of carefully controlled clinical trials.

Other intravesical treatments that have been used include resiniferatoxin, capsaicin, lignocaine, and oxybutynin. Evidence of their clinical efficacy however is lacking.

Neuromodulation

Sacral nerve stimulation is often used in the management of patients with detrusor overactivity. It is a minimally invasive procedure that involves stimulation of the S3 or S4 nerve root by a mild electric current. There is emerging evidence suggesting that it may be beneficial in the treatment of BPS/IC [8,19]. It is however still considered an investigational procedure and is not currently recommended for the treatment of BPS/IC.

Surgery

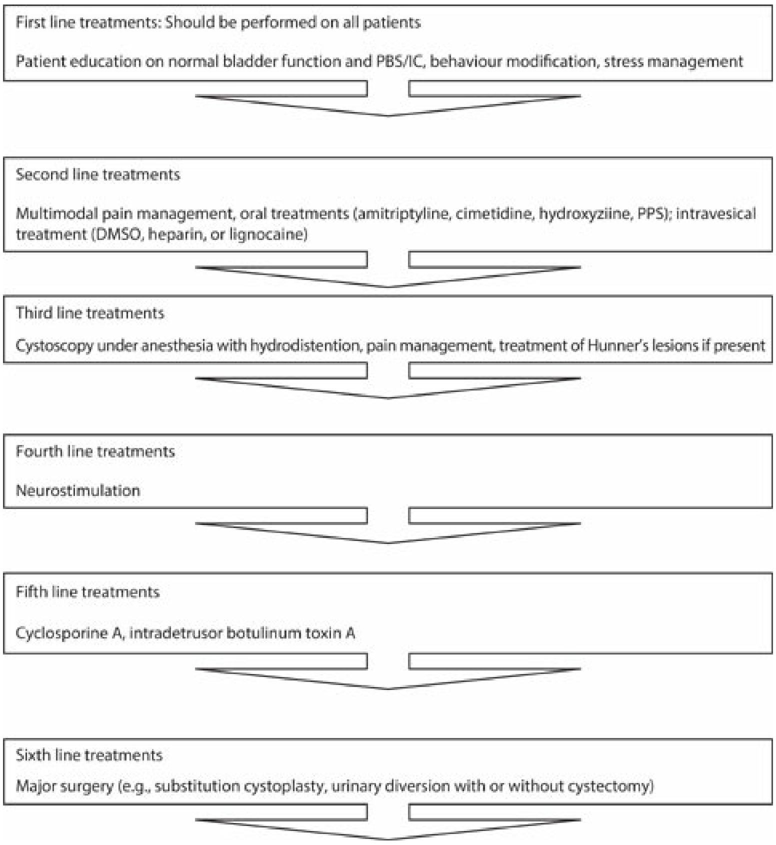
Surgery is reserved for severe cases that have refractory to all other treatment options. A urological opinion should be sought. Available surgical treatments include bladder augmentation cystoplasty, cystectomy, and urinary diversion.

CONCLUSION

BPS/IC is a chronic debilitating disorder. The etiology of the disease is unknown and it remains a diagnosis of exclusion.

Patients typically complain of pain in the bladder or pelvic area associated with urinary frequency or urgency. The diagnosis is heavily dependent on the history and physical examination as there is currently no specific diagnostic test for BPS/IC. Diagnostic adjuncts such as urinary analysis, urodynamics, and cystoscopy aid the diagnosis and exclusion of other confusable diseases.

Treatment is multimodal and often multidisciplinary. It includes patient education, which is fundamental. Management should commence with conservative measures such as behavioral modification and dietary modification followed by medical management with oral or intravesical therapy, which aims to provide symptomatic relief for pain and irritable bladder symptoms. More invasive treatments such as surgery should be reserved for refractory cases as they are associated with more morbidity. There is a limited role currently in clinical practice for neuromodulation and botulinum toxin. Although the results of available studies are promising, larger trials are required on the efficacy of these therapies. Further research into the etiology of the disease is required in order to correctly define a diagnostic criterion and management plan of the disease (Figure 55.6).



First line treatments: Should be performed on all patients
Patient education on normal bladder function and PBS/IC, behaviour modification, stress management
Second line treatments
Multimodal pain management, oral treatments (amitriptyline, cimetidine, hydroxyziine, PPS); intravesical treatment (DMSO, heparin, or lignocaine)
Third line treatments
Cystoscopy under anesthesia with hydrodistention, pain management, treatment of Hunner's lesions if present
Fourth line treatments
Neurostimulation
Fifth line treatments
Cyclosporine A, intradetrusor botulinum toxin A
Sixth line treatments
Major surgery (e.g., substitution cystoplasty, urinary diversion with or without cystectomy)

Figure 55.6 American Urological Association suggested approach for treatment of interstitial cystitis/bladder pain syndrome. (Adapted from Hanno, P.M. et al., *J. Urol*., 185, 2162, 2011.)

56 Bacterial Cystitis in Urogynecology: An Update

Nèvine I.D. te West and Kate H. Moore

INTRODUCTION

Urinary tract infections (UTIs) are traditionally divided into infections of the upper tract (pyelonephritis) and of the lower tract (bacterial cystitis). This chapter does not discuss upper tract infections, as knowledge on this subject is normally obtained during training in obstetrics. Untreated lower UTI may ascend to the kidneys and even be associated with septicemia; however, such events are beyond the remit of this chapter, which focuses on bacterial cystitis.

Cystitis is the general term used to describe inflammation of the urinary bladder. The subjects of interstitial cystitis (IC), cyclophosphamide cystitis, or rare parasitic infestations are not covered herein (but see Chapter 55). Bacterial cystitis is an inflammatory response to bacterial infection of the lower urinary tract. The hallmark symptoms and signs include dysuria and discolored, foul-smelling urine, suprapubic tenderness, urinary frequency, and urgency ± nocturia, which may be associated with microscopic or macroscopic hematuria and pyuria.

Bacterial cystitis may be acute, chronic, or recurrent as well as being simple or complex. The natural history is dependent on the type and virulence of the urinary pathogen, resistance to antimicrobial agents, and host defenses. Diagnosis in most simple cases is based on clinical symptoms, urine dipstick testing (which is controversial), preferably with laboratory confirmation by microscopy and/or culture. Management comprises identification of the causative organism and, based on the results of urine culture and sensitivity, at the same time prescription of an appropriate antimicrobial agent for a suitable length of time. In those women with recurrent or complex infections, more detailed strategies may be needed. This chapter examines the definition, epidemiology, and pathogenesis of bacterial cystitis and reviews the management of women presenting with both simple and complex lower UTIs. Current controversies regarding low-grade bacterial cystitis in refractory detrusor overactivity (DO) are also summarized.

DEFINITIONS

Bacteriuria

The term bacteriuria indicates the presence of bacteria in urine, because traditionally urine is thought to be sterile in normal individuals. When assessing the results of urine cultures, the clinician must distinguish between true bacteriuria and contamination of the urine as it passes through the distal urethral and introitus.

The term “significant bacteriuria” was first defined in the late 1950s by Kass, a Harvard nephrologist. His goal was to determine a quantitative threshold that would accurately distinguish true bacteriuria (which he defined as “actual residence of bacteria within the urine of the urinary tract”) from bacterial contamination (“the adventitious entry of bacteria into the urine during the collection of the specimen”) [1]. In 335 asymptomatic female outpatients, he identified two populations based on catheter specimens of urine: those with low bacterial counts (0–10^5 CFU/mL) and those with high counts (>10^5 CFU/mL). Bacteria cultured from the “low-count” group frequently showed commensal organisms and a repeat urine sample taken from them rarely matched the original specimen. In contrast, counts of >10^5 were more consistent on repeat testing and known urinary pathogens were commonly isolated. The relative degrees of pyuria were not reported. He concluded that “patients with more than 10^5 bacteria per mL of urine may be regarded as having true bacteriuria” [1,2].

Kass was mainly interested in preventing pyelonephritis. He compared asymptomatic women [1,3] with those having overt upper UTI [4,5]. It is worth remembering that in the 1940s and 1950s, pyelonephritis/infected shrunken kidney was found in 15%–20% of autopsy specimens and was a major cause of death in one third of these cases [4]. Although Kass defined $>10^5$ CFU/mL as "significant" bacteriuria (i.e., likely to result in morbidity), he did acknowledge that pyelonephritis may be associated with lesser degrees of bacteriuria in some situations. Sixty years later, despite the fact that Kass' threshold was not tested systematically on women with frequency/urgency/nocturia, his criterion of 10^5 CFU/mL of urine is still widely accepted as the definition of significant bacteriuria (i.e., infection) among symptomatic women [2,6].

Reevaluation in the 1980s by Stamm et al. later found that these criteria would in fact miss approximately half of patients with clinical symptoms of bacterial cystitis [7]. Therefore, he favored a diagnostic cutoff of $\geq 10^2$ CFU/mL. Tapsall et al. also demonstrated that patients with symptoms, but without significant bacteriuria, responded just as well to antibiotics as the group with significant bacteriuria [8]. Kunin reinforced the importance of low-count bacteriuria in a study assessing 639 women with and without symptoms of cystitis [9]. Of the symptomatic patients, 46% were found to have low-count bacteriuria (10^2–10^4 CFU/mL) compared to only 10% of the asymptomatic women. This study rejected the old hypothesis that urinary dilution contributes to low-count bacteriuria and concluded that low-count bacteriuria is actually just an early phase of infection [2].

The Infectious Diseases Society of America has since revised their guidelines accordingly [10], as has the European Association of Urology [11], recommending a threshold of 10^3 CFU/mL, as this improves the sensitivity without a significant loss of specificity. However, to date, most laboratories in the United Kingdom and Australia persist with the original diagnostic cutoff of 10^5 CFU/mL (unlike the United States and Europe that now employ the more stringent cutoff). Interestingly, the 2010 ICS/IUGA report on terminology defines UTI as "the finding of microbiological evidence of significant bacteriuria and pyuria usually accompanied by symptoms such as increased bladder sensation, urgency, frequency, dysuria, urgency urinary incontinence, and/or pain in the lower urinary tract" with suggested criteria of (1) bacteriuria >100,000 (10^5) colony-forming units (CFU)/mL on voided specimen or >1,000 (10^3) CFU/mL on catheterized specimen and (2) pyuria >10 white blood cell (WBC)/mm^3 [12]. This "traditional" threshold for significant bacteriuria on voided specimens now appears controversial.

Sterile Urine: Recent Evidence

Historically, the urine in the bladder is normally considered to be completely sterile, in that uropathogens are not detected using routine cultivation techniques. Older studies comparing suprapubic puncture specimens versus midstream urine samples revealed that incidences of significant bacteriuria on suprapubic catheter stab samples from asymptomatic women were less than 1% [13]. However, very recent studies in Europe and America using sophisticated techniques demonstrate that up to 35 genera of bacteria do in fact reside in the bladder of some women [14–17]. This research uses deep 16S rRNA gene sequencing and polymerase chain reaction (PCR) to identify various species of uncultivated bacteria in the urine [15]. Such specimens taken via transurethral catheters, suprapubic catheters, and voided samples from both symptomatic and asymptomatic women found bacterial DNA in urine from all three sampling methods. The microbial genera detected by PCR amplification in the transurethral catheter specimens corresponded to those obtained from suprapubic catheters. They appeared to be the true colonies of the bladder, as they differed greatly from the mixture of urinary and genital tract bacteria DNA found in the voided samples (which suggested contamination).

The same researchers went on to evaluate whether or not the bacteria found in the preliminary study could be grown in the lab [17]. Although 92% of samples showed no growth when cultivated at 10^3 CFU/mL using routine urine culture protocol, 80% grew bacteria when an expanded quantitative urine culture (EQUC) protocol was used (i.e., different types of agars in various aerobic and anaerobic conditions). Bacteria of 35 different genera and 85 species were present at levels below the cutoff used in standard culture protocols, which correlated with the 16S rRNA gene sequencing results. Thus, DNA studies show that viable bacteria inhabit the normal adult female bladder, in contrast with previous beliefs that the normal bladder is "sterile."

Pyuria

Traditionally, infection is distinguished from colonization by evidence of tissue injury/inflammation. In practical terms, this is indicated by the finding of pyuria [18]. Pyuria is present in most women with high-count UTIs [18,19]. However, the relationship between low-count bacteriuria 10^2–10^5 CFU/mL and pyuria is less clear [2]. Levels more than 10 leukocytes/mm^3 are considered pathological. However, the prevalence of pyuria increases with the concentration of bacteriuria, so that low-count bacteriuria is not always associated with pyuria [9,20]. For example, Stamm et al. [20] reported that incorporating pyuria into the diagnostic standard for acute infection (i.e., insisting on $>10^2$ CFU/mL plus pyuria) made little difference compared to quantification of bacteria alone [7]. The large case–control study by Kunin et al. established that the prevalence of pyuria (>20 WBC/mm^3) rises with the level of bacteriuria. This again supports the notion that low-count bacteriuria is just an early phase of classical bacterial cystitis [9].

Asymptomatic Bacteriuria

Asymptomatic bacteriuria (ABU) (i.e., the absence of dysuria, foul-smelling, discolored urine, loin pain, fever) is found in 1%–9% of young women and increases with age, reaching a prevalence of 14%–75% in the elderly or institutionalized [21]. Long-term ABU is defined as a persistent colonization of >3 weeks (to several years) of duration [21]. In general, treatment of ABU is not recommended, as routine antibiotics contribute to resistance as well as causing other adverse events and ABU may even be protective of recurrent UTI [22]. However, ABU requires treatment in circumstances such as pregnancy, instrumentation of the lower urinary tract, and renal transplant patients. *Escherichia coli* is the most commonly detected bacteria in ABU [21]. ABU with *Streptococcus agalactiae* (group B streptococcus) is common in pregnancy and requires treatment as it is associated with chorioamnionitis [23] and neonatal sepsis [24]. Note that group B streptococcus bacteria is increasingly recognized as a uropathogen (see later section).

Recurrent Bacterial Cystitis

This term describes symptomatic infections, which recur after a previous UTI, usually after treatment. It may be due to bacterial persistence or due to a new infection with the same or different bacteria. Risk factors for recurrent infection are shown in Table 56.1. Bacterial persistence often leads to frequent recurrence within days or weeks. The infection is usually by the original organism from a focus inside the urinary tract and is associated with an underlying anatomical problem [25]. Bacterial persistence may also occur if empiric treatment was given without proper urine culture and checking of the bacterial antibiotic sensitivity, or if the patient did not complete the antibiotic course, or if the bacteria developed resistance after the original (correct) treatment was started. In urogynecology patients (who often have coexisting incontinence or prolapse, voiding dysfunction, recent surgery, diverticula, etc.), the economically expedient practice of performing a simple dipstick and treating empirically cannot be recommended, as these patients are, by definition, prone to recurrence.

Table 56.1 Risk Factors for Recurrent Urinary Tract Infection

Lower urinary tract obstruction and chronic retention of urine
Bladder stones or intravesical foreign bodies
Trauma
Enterovesical and vesicovaginal fistulae
Urethral diverticula
Malformations of the urinary tract
Cystocele
Vesicoureteric reflux
Infected paraurethral glands
Contraceptive diaphragm use

Reinfection occurs after a prolonged interval (months) from the original infection and is often caused by a different organism [25]. Older studies found that about 80%–90% of recurrent cystitis is due to reinfection, of which about a third arose from the same organism invading the urothelium again [26].

Clinical Classification of Cystitis

In summary, UTIs as a whole are classified according to their location, clinical symptoms, and laboratory and microbiological findings, as shown in Table 56.2 modified from the European Association of Urology (EUA) guidelines [11].

Complicated UTI

Although this chapter primarily concerns bacterial cystitis, the urogynecologist must be constantly vigilant for what are described as "complicated" UTIs. As seen in Table 56.3, many "complicated" UTIs involve upper urinary tract, e.g., renal calculi and cysts, ureteric stricture, vesicoureteric reflux, ureteric stents, nephrostomy tubes, and renal transplants. However, the urogynecologist should be mindful that lower tract anomalies, e.g., bladder cancer, urethral stricture/diverticula, and urogenital fistula, incomplete emptying, and use of indwelling catheter, commonly feature sessile, non–*E. coli* organisms such as pseudomonas, which are frequently multiresistant organisms.

Table 56.2 Definitions of Cystitis Terminology

Description	**Clinical features**
Acute cystitis	
"Classical" uncomplicated bacterial cystitis	Significant bacteriuria > 10^5 CFU/mL with pyuria (>10 white blood cells per high power field)
Low-count/"occult" bacterial cystitis	Bacteriuria 10^3–10^5 CFU/mL ± pyuria
Recurrent UTI	Bacterial cystitis that reoccurs >3 times a year
Complicated UTI	UTIs associated with a condition that increases the risk of infection or of therapy failing (see Table 56.3)
Symptomatic UTI	Significant bacteriuria with dysuria, frequency, urgency, nocturia: foul-smelling urine, ± loin pain, febrile symptoms
Asymptomatic bacteriuria	Bacteriuria >10^5 CFU/mL of urine, without pyuria or symptoms

Table 56.3 Conditions Associated with Complicated Lower Urinary Tract Infection

Structural	Urolithiasis
	Malignancy
	Ureteric stricture
	Urethral stricture
	Bladder diverticula
	Renal cysts
	Fistulae
	Urinary diversions
Functional	Neurogenic bladder
	Vesicoureteric reflux
	Voiding difficulties (incomplete bladder emptying)
Foreign bodies	Indwelling catheter
	Ureteric stent
	Nephrostomy tube
Others	Diabetes mellitus
	Pregnancy
	Renal failure
	Renal transplant
	Immunosuppression
	Multidrug resistance
	Hospital-acquired (nosocomial) infection

PREVALENCE

Lower UTI is a common clinical diagnosis in developed countries and the most prevalent bacterial infection. Very little epidemiological data are available for bacterial cystitis alone; most prevalence data refer to "UTI" as a whole. Approximately half of all women will experience UTI sometime during their life, with an estimation of 150 million cases occurring a year worldwide [27]. Other than in the elderly, UTI is more common in women than in men. They account for 1%–3% of all general practitioner consultations in the United Kingdom [28] and 0.9% of all ambulatory appointments in the United States, with a total of 10.5 million visits noted in the United States in 2007 [29,30]. Recurrent cystitis is becoming a major problem, as 20%–30% of females with an acute UTI will have a recurrence within 3–4 months [31], and recurrence occurs in 48% of women who have had more than one episode [32]. Besides being distressing for patients, UTIs cause enormous health-care expense, mainly due to the high incidence. The costs of community-acquired UTI were totalled at $2.5 billion in the year 2000 in the United States [33]. With the increasing resistance to antibiotics, the costs are likely to rise.

Recently, ABU has received greater attention, partly because chronic infection in the elderly may be asymptomatic until it leads to fever. The prevalence varies greatly, from 1%–100% across different patient populations. "Healthy" women demonstrate a prevalence between 1% and 9% [21], with doubled risk in pregnant women (2%–15%) and threefold risk in diabetics (1%–30%). Although the elderly are particularly at risk of ABU, with the prevalence rising to 2%–50% and 14%–75% in the community-dwelling and institutionalized adults, respectively, morbidity and mortality are not increased. The prevalence of ABU is greatest in those with indwelling catheters (9%–100%).

PATHOGENESIS

As discussed earlier, urine is not "sterile," contradictory to what was originally thought. However, pathogenic bacteria must gain access to the bladder, generally from neighboring sites. The fecal–perineal–urethral route of infection is well documented. *E. coli* is the main causative organism, with the rectal flora serving as the main reservoir [34], explaining why fecal incontinence is associated with a higher risk of UTI [35]. Other colonization sites include the perineum, vaginal vestibule, urethra, and paraurethral tissues.

Traditionally, uropathogens are required to ascend the urethra, against the stream of urine, to colonize the bladder [34]. The mechanism of urethral ascension is still poorly understood. It may be facilitated by sexual intercourse or catheterization. The periurethral area is heavily colonized with bacteria. Urinary incontinence generally predisposes healthy postmenopausal women to develop recurrent cystitis [36]. The use of incontinence pads is associated with a significant increase in the incidence of symptomatic cystitis in the elderly [37].

However, just because bacteria gain access to the bladder, cystitis does not necessarily result. The bacteria must attach to the urothelial cells to begin the inflammatory process (see the succeeding text for more detail). Even virulent organisms require some degree of host susceptibility [38]. Patients with symptomatic bacteriuria are more likely to be neutropenic compared to those with ABU [39]. This study showed no difference in the virulence of the strains between the asymptomatic and symptomatic group nor any difference in resistance to antibiotics; thus, the authors suggested that host factors may be more important than bacterial virulence.

HOST DEFENSES

The bladder has several mechanisms to resist infection. Most important is the hydrokinetic or "washout" effect, in which diuresis and voiding act to dilute the bacterial load and wash away infecting organisms. In a 1969 study, 40% of women with bacteriuria became free of infection spontaneously within 12 months [40], while a 1971 study demonstrated that the urine of 80% of women with simple infections became sterile on placebo alone [41]. Thus, the risk of infection will depend on the size of the bacterial load, the multiplication rate of the organism, the urinary residual, the frequency of voiding, and the volume of fluid intake.

Antimicrobial Factors

The composition of urine may inhibit bacterial growth. Extremes of urine pH, high osmolality, and high urea concentration tend to be protective [42], which is why historically urine has been used as an antiseptic. Urea is the principal antibacterial electrolyte in urine, and its effect is also modulated by concentration and pH [43]. The acquisition of iron is also an important requirement for bacterial virulence, because bacteria need iron to grow. The *E. coli* bacteria is most studied in this regard [44], as it has been shown to upregulate the genes that control iron acquisition systems [45]. Urothelial cells that are invaded by *E. coli* respond by upregulating their own production of the transferrin receptor so as to prevent bacterial acquisition of iron [46].

Epithelial Factors

The inner (luminal) surface of the urothelium is lined by uroplakin membrane proteins that lie within the plasma membrane of the superficial urothelial cells (also known as umbrella cells). These uroplakin plaques are composed of four proteins (UPIa, UPIb, UPII, and UPIIIa) [47]. They form a permeability barrier, to prevent the resorption of urine solutes across the urothelium but also to limit the availability of receptors for bacterial adherence factors [48]. The urothelium is also coated by a proteoglycan mucin layer, which further reduces permeability. This acts to oppose bacterial colonization, partly due to the high negative charge of the sulfated and carboxylated glycosaminoglycans [49]. Unfortunately, uropathogens that express certain kinds of type 1 pili (mannose binding) can block this adherence barrier by binding to the UPIa protein (as it contains a high mannose content) using an adhesin protein called FimH [50]. Soluble factors normally found in the urine, such as Tamm–Horsfall protein, also protect the bladder. This mucoprotein is shed from the renal tubular cells and is excreted in the urine. It can bind and trap *E. coli*, partly by competing for the binding sites on the type 1 pili [51]. However, if the uropathogens are able to adhere to the urothelium, then the acute pathogenic cycle of bladder infection can begin.

Immunologic Factors

The fact that recurrent cystitis affects 20%–30% of women suggests that some women do not develop long-lasting protective adaptive immunity following their initial infection [52]. The reasons for this are unknown. The T helper (CD4+) cell adaptive responses to uropathogen infection are unknown, though CD8+ T cells are reportedly recruited to uropathogenic *E. coli* (UPEC)–infected bladders [53]. Secretory immunoglobulin A (IgA) is synthesized by plasma cells within the lamina propria of the bladder wall and hence provides a degree of humoral immunity. In addition, a significant proportion of IgA originates in the urethra and this may help prevent ascending infection [54]. Secretory IgA has also been shown to prevent microbial invasion by disrupting bacterial adherence [55], and production of IgA can be deficient in women with recurrent UTI [56].

When uropathogens bind to urothelium during the process of cystitis initiation, the bacteria induce production of C-reactive protein (CRP), leading to leukocyte influx, IgA production, and cytokine release, such as IL-6 and IL-8. These cytokines promote activation of CRP and mucosal IgA.

Toll-Like Receptors

If the initial defense mechanisms are resisted and the pathogen continues to attach itself to the epithelial cells, Toll-like receptors (TLR) are activated. These TLRs play an important role in the pathogenic cascade of UTI by the host [57]. This inhibits further invasion of the microorganism, induces the production of antimicrobial peptides, and initiates apoptotic pathways, so that infected cells are exfoliated and pro-inflammatory chemokines are released, triggering neutrophil accumulation [42]. Defects in TLR pathway genes are associated with bacteriuria [57].

ROLE OF THE BACTERIAL PATHOGEN

Uropathogens have the ability to survive and multiply in the bladder as well as being able to adhere to the bladder epithelium. These unique qualities make them particularly virulent.

Adherence

The ability of bacteria to adhere to the urothelium of the lower urinary tract is an important initial step in the pathogenesis of lower UTI. The *E. coli* uropathogen has been the most widely studied, because it possesses type 1 fimbriae, which are essential for the invasion of *E. coli* into the bladder epithelial cells (Figure 56.1) [42]. *E. coli*, which do not have these type 1 fimbriae, are unable to infect the urothelium.

These fimbriae receptors bind to the surface uroplakins and other cellular proteins, thus preventing washout by the shear forces of the urine cascading across them. In animal models and one human study [58], *E. coli* are then shown to actually live inside the urothelial cells, forming intracellular bacterial communities (IBCs) unless the release of cytokines can provoke shedding of the urothelium and washout. Once the IBCs become established in the superficial umbrella cells, they can invade the lower layers of the urothelium and can become impervious to antibiotic treatment.

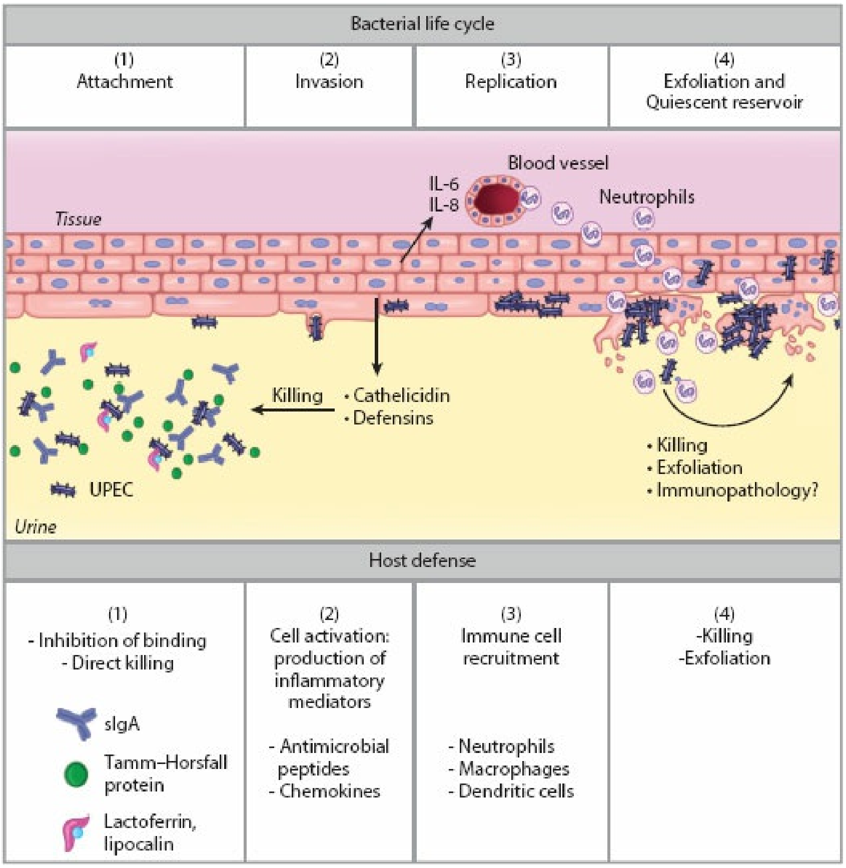

Figure 56.1 Multilayered effector mechanisms to combat urinary tract infections. Soluble factors like lactoferrin, Tamm–Horsfall protein (THP), or secretory IgA inhibit attachment of uropathogenic *Escherichia coli* to the epithelium. Despite these defense mechanisms, some bacteria are able to attach and invade the epithelium, which in turn releases antimicrobial molecules like cathelicidin or defensins. Moreover, the uroepithelium produces interleukin (IL)-6 and IL-8 to attract additional immunocompetent cells like neutrophils, which help to eliminate the pathogens. (Reprinted from Weichhart T, Haidinger M, Horl WH et al.: Current concepts of molecular defense mechanisms operative during urinary tract infection. *Eur J Clin Invest*. 2008. 38(Suppl 2). 29–38. Copyright Wiley-VCH Verlag GmbH & Co. KGaA. Reproduced with permission.)

Uropathogens: Structure and Function

UPECs are the most common cause of UTI in the United States and abroad; they are responsible for about 80% of community-acquired cystitis and 25% of hospital-acquired infection. These are followed in the prevalence by *Staphylococcus saprophyticus* (10%–15% of community infections) and then *Klebsiella*, *Enterobacter*, *Proteus*, and *Enterococcus* species [34]. UPECs possess a number of structural factors that enhance their ability to adhere to and colonize the urothelium. Most important are adhesive fibers known as pili, or fimbriae, which live on the bacterial outer membrane [34,59]. Different types of UPEC strains are able to assemble different types of fimbriae, which recognize specific receptors on the urothelium, and enable strong adherence to the cell.

For example, FimH (on type 1 pili) binds to uroplakin 1a, which has mannose as one of its components (this is relevant to cranberry treatment, discussed later in this chapter). Type 1 pili also bind to the TLR 4. The presence of FimH-adhesive molecule is very important for triggering acute inflammation (and symptoms of pain); *E. coli* that do not have FimH tend to be nonadherent and they are often found in ABU [34,60,61].

RISK FACTORS FOR UTI

Host factors are certainly of equal importance with bacterial virulence in terms of the risk of developing cystitis. Host factors are considered in terms of congenital anomalies (such as vesicoureteric reflux, ectopic ureter, megaureter, or meningomyelocele) and acquired causes (Table 56.4). Other risk factors include a history of childhood UTI and a maternal history of UTI [34].

Age

Among children, the incidence of UTI is highest in the first year of life, with a gradual decrease to low rates at 11–15 years. Low-grade vesicoureteric reflux is an important factor. During a voiding detrusor contraction, if the vesicoureteric valves are incompetent, reflux of bladder urine up into the ureters/renal pelvis may occur. When the detrusor relaxes again, stagnant urine drains back from the upper renal tracts into the bladder, which predisposes to infection. In a review of 200 girls with recurrent lower UTI, 43% demonstrated vesicoureteric reflux, whereas in those with only one episode of infection, the corresponding rate was 36% [62].

Young girls with recurrent UTI and day wetting (likely due to DO) are known to adopt a posture of kneeling down on their heel (“the curtsy sign”) to stop urgency incontinence, which is thought to promote reflux of nonsterile urine from the lower urethra back up into the bladder [63]. This may be associated with irregular or “staccato” voiding patterns and incomplete emptying, which promotes UTI.

Table 56.4 Acquired Risk Factors for Urinary Tract Infection

Traumatic	Surgery (urinary diversion, clam cystoplasty)
	Sexual intercourse
	Sexual abuse
	Foreign bodies (catheters, stents, mesh)
	Contraceptive diaphragm
Inflammatory	Vulvourethritis
	Chronic inflammation (tuberculosis, syphilis, schistosomiasis)
	Interstitial cystitis
	Radiotherapy
	Fistula
Metabolic	Calculi
	Diabetes mellitus
Drugs	Cyclophosphamide
	Tiaprofenic acid
Anatomic	Cystocele
	Urethral diverticulum
Functional	Detrusor hypotonia
	Detrusor dyssynergia
	Constipation
Malignancy	Bladder tumors
	Other pelvic tumors (cervix, uterus, ovary)

The incidence of UTI increases in young adult women, where sexual activity is an important contributory factor, and increases again in old age. Reduced estrogen levels following the menopause are associated with vaginal flora changes. *Lactobacilli* that belong to the normal microflora of the vagina decline, which is associated with a rise in pH, allowing growth of Gram-negative bacteria increasing the risk of UTI [64]. UTIs in the elderly are common, accounting for approximately 25% of all infections [31] and 30% of those found in nursing homes [65]. The increasing prevalence of lower UTI in old age is most likely to be multifactorial in nature and is associated with a history of UTI, the presence of concomitant systemic disease, diabetes, increasing immobility, fecal and urinary dysfunction, the presence of a cystocele, instrumentation of the urinary tract, and sexual activity (although the association is less strong than in younger women) [66].

Persistent bacteriuria is not associated with significant morbidity [35] and it has a low predictive value for identifying febrile UTIs [67]. In part, this is because bacteriuria with low-virulence Gram-positive bacteria such as enterococci, coagulase-negative staphylococci, and group B streptococci are more common in this age group [21]. ABU is very common in the elderly with up to 75% of institutionalized women found to be bacteriuric [21] and treatment is not proven to be generally helpful [68]. However, UTI in the elderly can provoke fever, confusion, nausea, vomiting, dehydration, and delirium without bladder symptoms [69]. Predictive factors include severe cognitive impairment, disability in daily living, and self-reported urinary incontinence. Antibiotics must be used with particular care in the elderly because of the risk of *Clostridium difficile*.

Obesity

Studies on the association between obesity and UTI have shown contradicting results. In a large study of the factors influencing the rate of first referral for urinary infection in 17,032 women, the risk of first infection was higher in the nonobese compared to the obese [70]. A larger study of insurance claims for UTI treatment in 95,598 patients found obese women likely to be diagnosed with UTI [71]. Several studies have shown that obese patients are more at risk of developing UTIs after surgery than nonobese patients [72].

Behavioral Factors

Factors such as adequate fluid intake, voiding habits, diet, synthetic underwear, and use of perfumed soaps and bubble baths may be associated with the development of UTIs [73]. Sexual intercourse increases the risk of UTI by 90%, which increases even more with the uses of condoms [74]. Furthermore, the frequency of intercourse has also been shown to be a significant risk factor [75] and certain strains of *E. coli* may be transmitted between partners [76,77]. Theoretically, anal sex may be associated with increased risk of UTI; however, there is no literature to support this.

Instrumentation of the Urinary Tract

One of the most common forms of complicated UTI is related to the use of catheterization. The incidence of bacteriuria associated with an indwelling urinary catheter is 3%–10% per day, duration of catheterization being the most important risk factor for infection [30]. Following catheter removal, the bacteriuria will resolve spontaneously in around a third of cases [78]. While fewer than 5% of catheter-associated UTIs result in bacteremia, they are nevertheless a significant cause of morbidity, and they are also an important reservoir of antibiotic-resistant bacteria in hospitals and nursing homes. The frequency of catheter-acquired infection increases with the duration of catheterization and the failure to maintain a closed drainage system. Consequently, it is not uncommon that infections with multiple organisms occur in women with long-term indwelling catheters.

The prevalence of bacteriuria in the literature ranges from 9% to 100% [21]. *Klebsiella*, *Pseudomonas*, and *Enterobacter* are more prevalent as well as *Morganella morganii*, which is rarely found in other subgroups. UK and American evidence-based guidelines for preventing infections and treating catheter-associated UTIs have been published [79,80]. Using interventions such as topical antimicrobials, disinfectants added to the urinary drainage bag, antimicrobial coatings for catheters, or antimicrobial irrigation do not decrease the incidence of catheter-associated infections [79]. A study looked at different rates of UTI after various types of catheters (nitrofurazone-impregnated silicone catheter, standard PTFE-coated latex catheters, and silver alloy–coated hydrogel latex), but did not show any significant difference between them [81]. Bacteriuria should be expected in women with long-term catheterization, and, if asymptomatic, treatment is generally not justified as it is unlikely to give a microbiological cure and risks selecting for antibiotic-resistant microorganisms [79]. Catheters should be removed at the earliest opportunity and changed on a regular basis, as microbial colonization is inevitable over time.

As an alternative to long-term catheterization, the technique of clean intermittent self-catheterization (CISC) may be considered in women who are able to learn the technique, as it significantly reduces bacteriuria [82]. Evidence, however, would suggest that the use of prophylactic antibiotics does not improve the outcome in women performing CISC and should not be used.

Suprapubic catheterization (SPC) as an alternative method of long- or short-term bladder drainage is associated with lower infection rates. A recent study of post urogynecology surgery studied the insertion of indwelling urethral catheters for 24 and 90 hours, versus SPC for 90 hours, and found no significant difference between the three groups in the incidence of symptomatic UTI, but ABU was significantly less in the SPC group [83]. The suprapubic route has the added advantage of allowing women to void with the catheter in situ and have postvoid residuals checked without the need for repeated urethral catheterization. The rate of bacteriuria in the literature following cystoscopy ranges from 2.8% to 21% [84]. Bacteriuria can be lowered by a single dose of antibiotic prophylaxis such as gentamicin, but the risk of side effects should be considered as the majority will not develop UTI symptoms.

Voiding Dysfunction

Incomplete emptying of the bladder is an important cause of UTI [63]. It is usually secondary to detrusor failure or hypotonia but can be associated with detrusor–sphincter dyssynergia or outflow obstruction secondary to a pelvic mass, significant cystocele, surgery, or urethral stricture. As regards hypotonia, urodynamic studies have shown that, with increasing age, there is a significant increase in postvoid residual and a decrease in urinary flow rates, voided volume, and bladder capacity [85]. This would suggest that voiding function deteriorates with age and may be partly responsible for the increased incidence of UTI in the elderly. Postpartum bladder hypotonia following unrecognized overdistension is a major problem that can affect UTI risk long term.

CAUSATIVE ORGANISMS AND ANTIBIOTIC RESISTANCE

Gram-negative coliform bacilli of the family *Enterobacteriaceae* account for over 70% of cases, and *E. coli* (Figure 56.2) remains the predominant species in both primary care (approximately 70%) [86,87] and hospital practice (56%) [88]. *Proteus mirabilis*, *Enterococcus faecalis*, and *Klebsiella pneumonia* are the most prevalent hereafter (3%–8%) and are found twice as often in hospital-acquired UTIs and in patients over 65 years of the age [88]. Antibiotic-resistant noncoliform Gram-negative bacilli such as *Pseudomonas aeruginosa* and *Acinetobacter* species occur almost exclusively in hospital-acquired infections. Among Gram-positive bacteria, *S. saprophyticus* is an important cause of UTI in sexually active women. Although mainly known for its association with neonatal disease, *S. agalactiae* (group B streptococcus) is also a known uropathogen that is increasingly being reported [89], particularly in the elderly with chronic diseases [90]. The other coagulase-negative staphylococci, and *Staphylococcus aureus*, are more commonly hospital associated, apart from contaminated collections. Fastidious bacteria that can only be isolated on enriched culture media, including *Streptococcus pneumoniae* and *Haemophilus influenzae*, occasionally cause UTI in primary care.

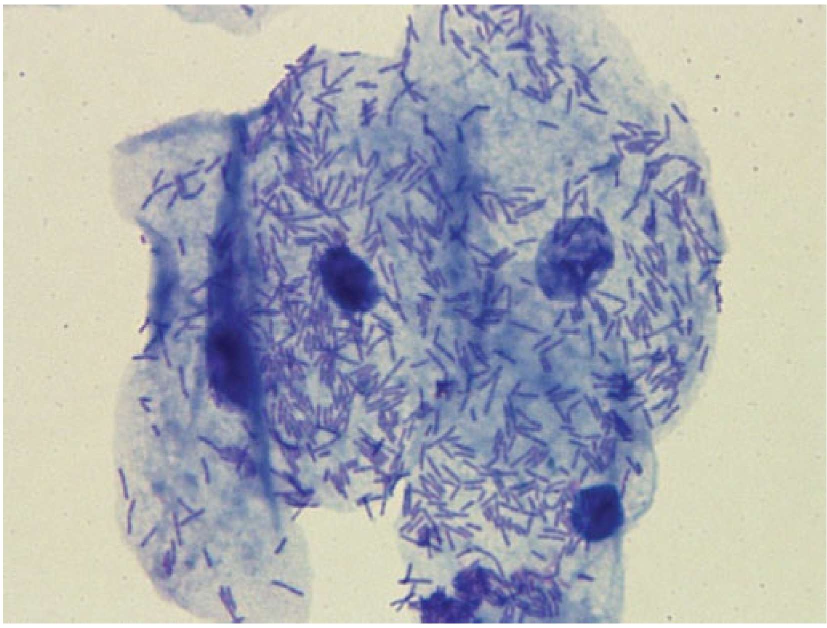

Figure 56.2 Urothelial cells associated *Escherichia coli* (Wright stain).

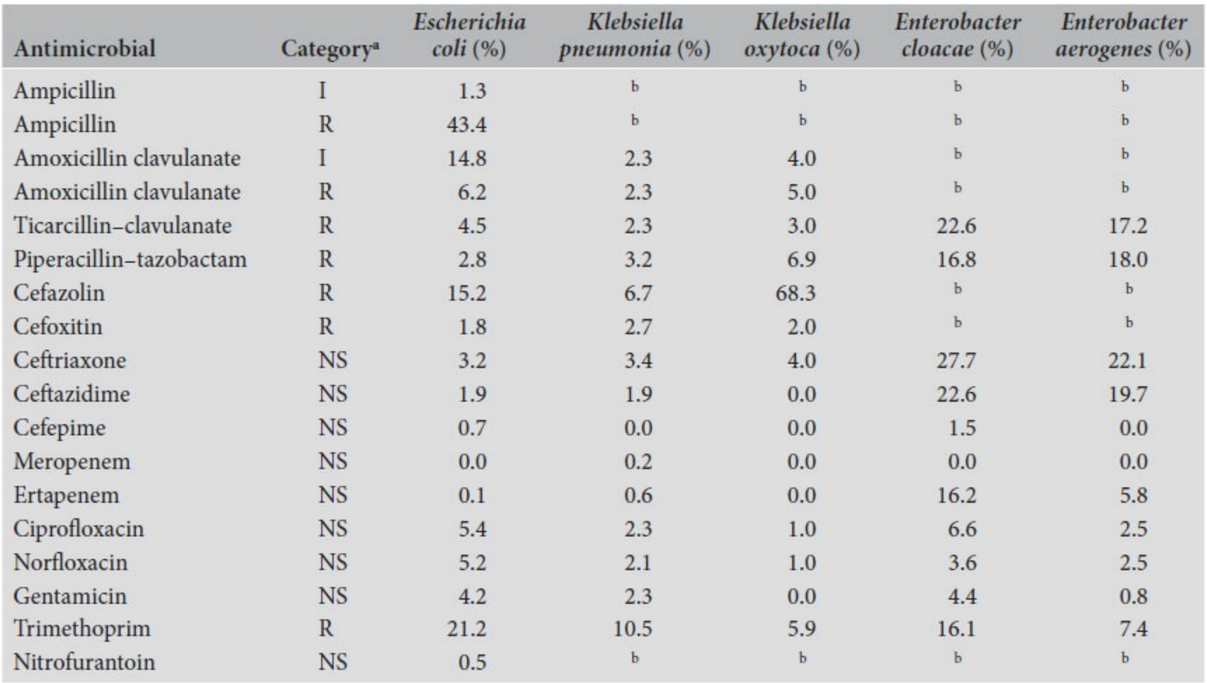
Bacteria that require special detection techniques, such as the cell wall-deficient mycoplasma (including *Ureaplasma urealyticum*) and the obligate intracellular pathogen *Chlamydia trachomatis*, are also recognized causes of cystitis. UTI can also be caused by microorganisms other than bacteria. Lower UTI due to *Candida* species is most common in patients with urinary catheters and usually reflects colonization of the catheter. Cystitis due to viruses such as polyoma and adenoviruses occasionally occurs in immunocompromised patients, especially those who have undergone renal or bone marrow transplantation.

Emerging Antibiotic Resistance

The global threat from increasing prevalence of resistance to antimicrobials among uropathogens has been reported by the World Health Organization in 2014 [91]. Rates of resistance to the commonly used oral antimicrobial agents vary between countries depending on the availability and usage of different compounds. To date, cystitis has been a relatively simple condition to treat with the available antibacterial drugs, although increasing resistance is a major concern [34,92]. The susceptibility of *E. coli* to nitrofurantoin is still high (96%–100%) [87,88]. A recent study in a general practice setting in France showed high levels of susceptibility to fosfomycin (99%), ofloxacin (97%), trimethoprim–sulfamethoxazole (87%), and amoxicillin/clavulanic acid (91%) [87]. However, increasing resistance to the traditional first-line therapy, trimethoprim–sulfamethoxazole has led to wider use of fluoroquinolones with resultant increasing bacterial resistance against norfloxacin and ciprofloxacin. An Australian study on acute pyelonephritis, which spanned 12 years, demonstrated increasing resistance of *E. coli* strains to a variety of antibiotics, with stable prevalence of resistance to ampicillin/amoxicillin between 40% and 50% [86]. Although resistance to first- and third-generation cephalosporins in *E. coli* is low, it is rising, particularly in those elderly, who have been admitted to hospital, require indwelling catheters, or are residents of nursing homes. Most community-derived urinary isolates remain susceptible to cephalosporins and co-amoxiclav, although this is not the case in hospitals where cephalosporinase-producing species such as *Enterobacter* are more common in addition to the acquired resistance to those antibiotics.

The emergence and spread of plasmid-borne extended-spectrum beta-lactamase (ESBL) genes that confer resistance to penicillins combined with clavulanate or sulbactam and third-generation cephalosporins in *Enterobacteriaceae* and other Gram-negative bacteria present a growing problem. The mobile plasmids containing these genes may also carry genes that confer resistance to other classes of antibiotics including aminoglycosides, folate antagonists, and quinolones, so their spread may be influenced by antibiotics prescribed for any condition, including UTI. The genes encoding these enzymes are readily transferred between species so that cross-infection is not recognized simply by a rising rate of antibiotic resistance within one species. Community-acquired UTIs with ESBL-producing bacteria that are resistant to all oral antibiotics are already being encountered and pose real therapeutic difficulties. Nonsusceptibilities and resistances are demonstrated in Table 56.5 [93].

Table 56.5 Nonsusceptibility and Resistance Rates for the Main Species Tested



Antimicrobial	Category[a]	*Escherichia coli* (%)	*Klebsiella pneumonia* (%)	*Klebsiella oxytoca* (%)	*Enterobacter cloacae* (%)	*Enterobacter aerogenes* (%)
Ampicillin	I	1.3	[b]	[b]	[b]	[b]

[a] R, resistant; I, intermediate; NS, nonsusceptible (intermediate + resistant).

[b] Considered largely intrinsically resistant due to natural β-lactamases.

Hospital- vs. Community-Acquired Infections

Community-acquired infections differ from those originating from within the hospital environment where *Klebsiella, Staphylococcus*, and *Pseudomonas* are more prevalent [88]. The frequency of various species causing community- and hospital-acquired UTIs cultured in the United Kingdom is demonstrated in Table 56.6 [88].

INVESTIGATIONS

Microbiologic Investigations

In primary care, the diagnosis of UTI is often made on clinical grounds, possibly supported by point-of-care dipstick urinalysis. This is not generally appropriate in a urogynecology service partly because bacterial toxins are known to enhance detrusor contractility [94,95] and inflammation can weaken urethral sphincter strength [96], thus worsening incontinence, but also because precise accurate treatment is required before placing urodynamic catheters or commencing urogynecology surgery. Furthermore, Khasriya et al. have recently highlighted the low sensitivity and specificity of dipstick urinalysis as well as microscopic examination for pyuria [97]. They compare both these tests to urine culture of both midstream and catheter specimens. The sensitivity of leukocyte esterase (LE) and microscopic pyuria was 56% and that of nitrite 10%. They emphasize the unreliability of dipstick urinalysis in diagnosing UTIs. Moreover, in patients with urinary symptoms associated with low bacterial counts, the sensitivity of combined LE and nitrite testing may be as low as 25% [73].

Microscopy and Culture

Phase contrast microscopy is mainly used to quantify leukocytes and erythrocytes and detect squamous epithelial cells (urethral) and bacteria. Gram staining can be a useful alternative; the presence of bacteria can be confirmed and indicative of the causative microorganism. Selective media used to culture urine routinely (e.g., cysteine lactose electrolyte-deficient [CLED], MacConkey, and chromogenic agars) are selected to enhance colonial morphology and distinguish mixed from pure growth of common uropathogens. Blood agar will support growth of more fastidious organisms that may not otherwise be recognized. Figure 56.3 illustrates *E. coli*, growing on horse blood and MacConkey agars. Even *Neisseria gonorrhoeae* has been isolated from urine samples when cultured on appropriate media. Liaison between the requesting clinician and the laboratory is essential to ensure optimal investigation.

Table 56.6 Relative Frequency (% of Total) of Isolation of Species Causing Various Types of UTI

Community-acquired UTI (patients < 65 years)(*n* = 397)	**Community-acquired UTI (patients > 65 years)(*n* = 392)**	**Hospital patient UTI (excluding pyelonephritis) (*n* = 394)**

Further Investigations

In the majority of women with a single episode of simple acute cystitis, there is no need for further investigation. However, women with proven recurrent cystitis and those with a childhood history of UTI, persistent infection that does not respond to therapy, or persistent hematuria warrant further investigation.

Renal function should be assessed with serum creatinine, urea, and electrolytes. In specific cases, it may be helpful to exclude atypical infections (*Mycoplasma hominis*, *U. urealyticum*, and *C. trachomatis*). The usual history is of a woman suffering repeated cystitis episodes, which improve with antibiotics, but symptoms return as soon as antibiotics are stopped. Often, there have been repeated MSUs that demonstrate a sterile pyuria, but no growth on culture. One study found a positive culture for ureaplasma in 26% of the specimens tested for atypical organisms and 7.6% revealed ureaplasma and mycoplasma [98]. They were cultured in 4.3% of patients with sterile pyuria. Although the numbers are small, an improvement rate of 71% was found with 3 months of antibiotics (norfloxacin in most patients).

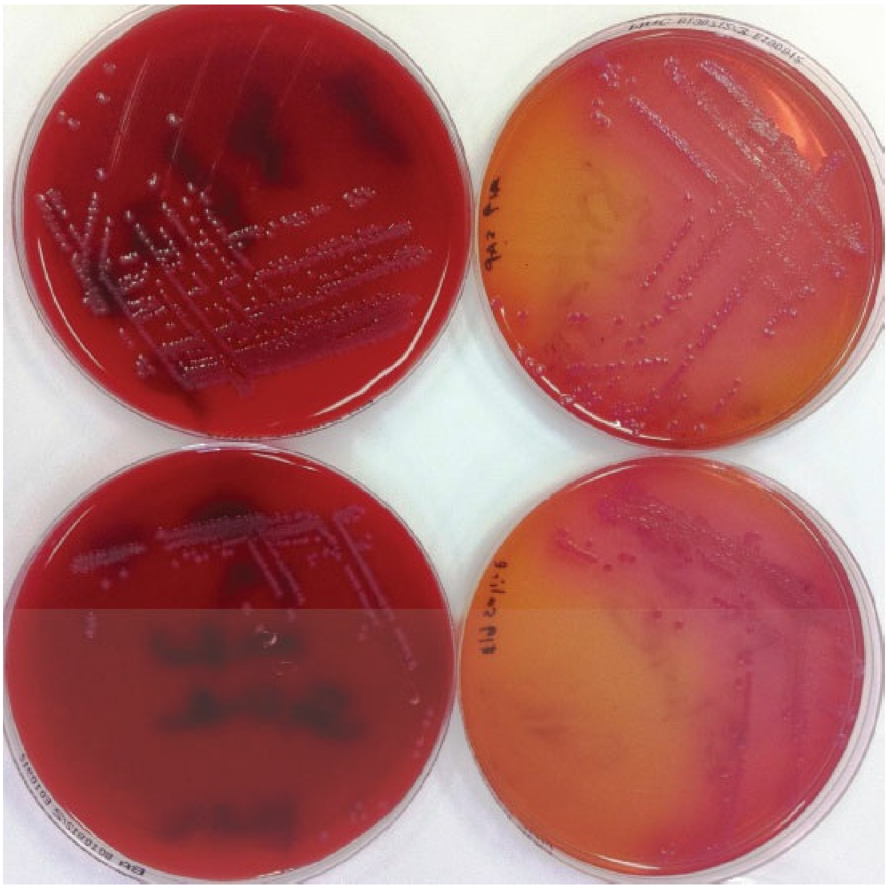

Figure 56.3 Escherichia coli growing on horse blood (left) and MacConkey (right) agars.

Ultrasound of the entire renal tract to eliminate hydronephrosis or calculi, with post–micturition scan to exclude residual >100 mL, is important. Pelvic ultrasound to rule out pelvic mass is worthwhile at the same time. The upper tracts can be imaged using CT urography, which has largely replaced intravenous pyelograms [99]. Renal imaging on dimercaptosuccinic acid scan may be needed in protracted or recurrent upper tract infection. Mercaptoacetyl triglycine and technetium-labeled diethyltriaminepentaacetic acid may also be considered in order to exclude both upper urinary tract obstruction and renal scarring.

Women with recurrent UTI not responding to simple prophylactic measures (see in the succeeding text) or those with hematuria should undergo cystoscopy (although if urine cytology is positive, this should be done by a urologist). Follicular cystitis (Figure 56.4), which may indicate IBCs, can benefit clinically from diathermy to these lesions, but this has not been systematically reviewed. Evidence of perforation of the bladder by a previous continence procedure (i.e., TVT) needs careful scrutiny with a 70-degree telescope, as this may cause recurrent UTI that is resistant to any therapy. Search for the lumen of a urethral diverticulum requires meticulous examination with a cystourethroscope (after MRI scan).

TREATMENT

Management of bacterial cystitis is aimed at treating the current infection, with eradication of clinical symptoms and microbiologically significant bacteriuria/pyuria, and preventing further recurrences, by correcting risk factors and instigating a prophylactic regime where needed.

General Measures

Patients with acute cystitis should be encouraged to increase their fluid intake in order to achieve a short voiding interval and a high flow rate, which will help to dilute and flush out the infecting organism. Symptomatic relief may be provided by alkalinization of the urine, drinking a large teaspoon of bicarbonate of soda (or commercial preparations, e.g., Ural) in a glass of water every 3–4 hours for 2–3 days. With such measures, spontaneous remission of symptoms may occur in up to 40% of women [100], although in the urogynecology patient with associated pelvic dysfunction, a urine culture should be performed and appropriate antibiotics should be given if symptoms are not greatly resolved when the culture result is known. The common practice of patients simply alkalinizing and diluting the urine is fraught with difficulty in those with coexistent cystocele or incontinence.

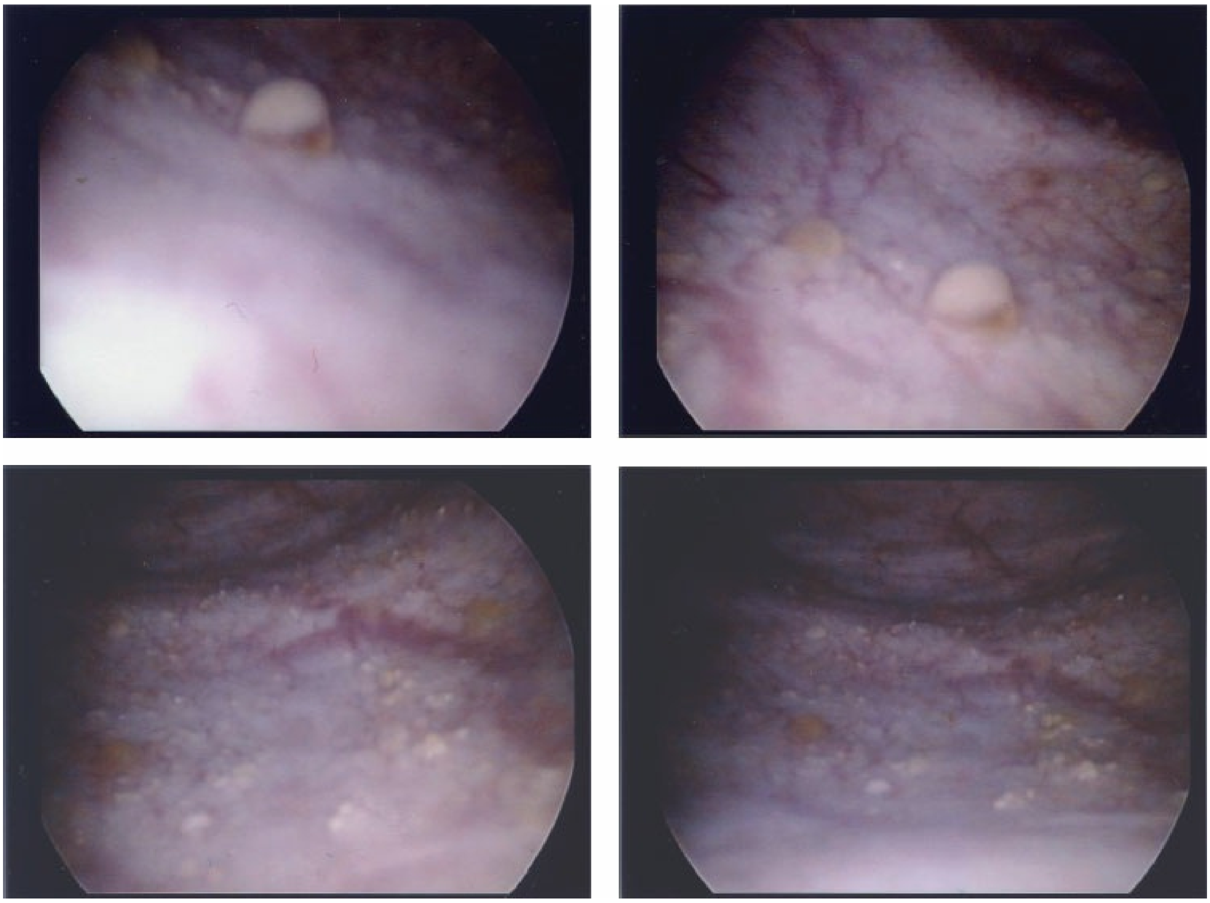

Figure 56.4 Follicular cystitis seen during cystoscopy performed for recurrent urinary tract infections.

ANTIMICROBIAL THERAPY

Ideally, drugs should be reliably absorbed after oral administration, safe, and well tolerated. Where the pathogen is known, the most precise antibiotic should be used. When treating an acute episode of cystitis encountered in the urogynecology clinic, the antibiotic with the greatest likelihood of eradicating the most common organism (*E. coli*) appears to be nitrofurantoin (100% susceptibility) [87]. Because it is highly concentrated in the urine but serum and tissue levels are subtherapeutic, it does not generally cause vaginal monilia; however, it cannot be used to treat pyelonephritis [101]. It has a complex mode of action, so that acquired resistance is uncommon [101,102]. Importantly, nitrofurantoin is one of few oral antibiotics for cystitis due to ESBL-producing organisms alongside fosfomycin and pivmecillinam with susceptibilities of 94%, 97%, and 85%, respectively [103]. Adverse effects other than nausea are rare and this can be contained by taking the drug with food, which also increases the absorption of nitrofurantoin and the duration of therapeutic levels [101]. The macrocrystalline formation, such as in macrodantin, slows absorption, which reduces nausea and vomiting.

Many of the antibiotics that were most commonly used to treat UTIs now have to be used with caution, either because resistance rates among uropathogens are high (as in the case of amoxicillin and trimethoprim) or because of the association with *C. difficile* (as in the case of cephalosporins and quinolones).

Undue emphasis is often placed on the distinction between bactericidal and bacteriostatic antibiotics. In most cases, it makes no difference to outcome. However, bactericidal antibiotics are preferred on theoretical grounds for patients with immunodeficiencies. Of the antibiotics commonly used to treat UTIs, the β-lactam antibiotics and aminoglycosides and fluoroquinolones are the most reliably bactericidal.

Individual Antibiotics

Nitrofurantoin

Nitrofurantoin is excreted in urine in high concentrations and has little action systemically. It is converted by bacterial nitrofuran reductase to active forms that attack ribosomal proteins, DNA, and other macromolecules. Resistance to this agent is uncommon and may be chromosomal or plasmid mediated. There may be antagonism with quinolones if taken in combination. This agent is generally regarded as a urinary antiseptic because of its negligible tissue penetration and low blood levels.

Although nitrofurantoin is highly effective against *E. coli*, *Klebsiella* and *Enterobacter* sp., and *Streptococcus* in acid urine, it has no effect at all against *Proteus* or *Pseudomonas* species as these organisms split urea-producing ammonia and an alkaline urine.

Nitrofurantoin is safe during pregnancy, but is contraindicated at term because of the risk of causing neonatal hemolysis. Nitrofurantoin is used in caution in the elderly, due to it being contraindicated in patients with renal insufficiency. Recent data have proven its use to be both effective and safe in those with a creatinine clearance greater than 40 mL/min [66].

Amoxicillin

Amoxicillin is a derivative of ampicillin that has a similar antibacterial spectrum but is better and more reliably absorbed. Both antibiotics contain a β-lactam ring and are effective against Gram-negative and Gram-positive organisms, targeting the cross-linkages of the bacterial cell wall, and are destroyed by bacterial beta-lactamase. These drugs are no longer recommended as first-line empiric therapy for UTIs because of the high prevalence of resistance among *Enterobacteriaceae*. Augmentin (co-amoxiclav) is a combination of amoxicillin and clavulanic acid that inhibits the β-lactamase enzymes produced by many amoxicillin-resistant bacteria. Augmentin has a spectrum of antibacterial activity suitable for treating UTIs as it is also effective against Gram-positive pathogens. Although co-amoxiclav use has been associated with *C. difficile*, the association may be less strong than with cephalosporins. Co-amoxiclav has therefore superseded second-generation cephalosporins in many hospitals, but it should still be used with caution, especially in the elderly [104].

Cephalosporins

Cephalosporins act in a similar fashion to penicillins by targeting the cross-linkages of the bacterial cell wall to prevent replication and weaken the rigid structure allowing cell death by lysis. First-generation cephalosporins are effective against most community-associated uropathogens, but they are not active against enterococci, *Enterobacter*, and *Pseudomonas*. Although serum levels of first-generation cephalosporins are poor after oral administration, they appear in high concentrations in urine, so they are useful for cystitis but not pyelonephritis. For treating UTIs, the newer and more expensive second-generation oral cephalosporins offer little or no benefits over the earlier (and cheaper) cephalosporins. The third-generation cephalosporins are resistant to the effects of simple beta-lactamases and have found widespread use in empiric therapy for acute urosepsis often in combination with an aminoglycoside.

Trimethoprim

Trimethoprim blocks the folic acid metabolic pathway in bacteria and was widely used as first-line empiric therapy for UTIs; however, resistance is increasing even in the community. Trimethoprim is best avoided in pregnancy (especially first trimester), because of the theoretical risk of teratogenicity. Co-trimoxazole (Bactrim) is a mixture of trimethoprim and sulfamethoxazole, rarely offers any benefits over trimethoprim, but has a higher risk of side effects. The U.K. Committee for Safety of Medicines recommends that co-trimoxazole should be used only where there is good bacteriologic evidence of benefit over trimethoprim.

Tetracyclines

Tetracyclines cover 50%–90% of most uropathogens, including atypical microorganisms. They are bacteriostatic and act on the bacterial ribosome to block protein synthesis. Other than doxycycline and minocycline, they are excreted mainly in the urine. However, they are little used for treating UTIs, and they are deposited in growing bones and teeth and are contraindicated in pregnancy, breastfeeding women, and children aged <12 years.

Fluoroquinolones

Fluoroquinolones block bacterial DNA replication and include ciprofloxacin, ofloxacin, and norfloxacin. Ciprofloxacin is the only orally effective antibiotic against *P. aeruginosa*. Because high drug concentrations occur in urine, they may be effective in UTIs due to Gram-positive bacteria, although they are not the recommended first-line therapy for these infections. They are contraindicated in pregnancy and recommended for use in children only where there is no alternative. Nalidixic acid is an older quinolone antibiotic that is inactive against *P. aeruginosa* and is no longer used.

Carbapenems

Carbapenems are related to β-lactam antibiotics and have found a niche as a reserve antibiotic for treating antibiotic-resistant bacteria. These are expensive very broad-spectrum β-lactam antibiotics that are for intravenous use only. Their main use in treating UTIs is in treating infections with ESBL-producing Gram-negative bacteria, including strains that are resistant to other antibiotic classes such as the fluoroquinolones and aminoglycosides. Meropenem and imipenem with cilastatin are the most commonly used carbapenems for hospital inpatients. Ertapenem is another carbapenem antibiotic. Unlike meropenem and imipenem, cilastatin has no useful antipseudomonal activity, but it has a longer half-life, permitting once daily administration so that it can be used for outpatient therapy of infections with multiresistant bacteria such as ESBL producers.

Piperacillin–Tazobactam

This is a combination of piperacillin (an antipseudomonal penicillin) and tazobactam (a β-lactamase inhibitor). It has an antibacterial spectrum that is similar to co-amoxiclav, together with activity against *P. aeruginosa*. It appears to be much less likely to select for *C. difficile* than the broad-spectrum cephalosporins and has largely superseded their use in many hospitals.

Aminoglycosides

Aminoglycosides such as gentamicin and amikacin have been used to treat serious infections, especially with Gram-negative bacteria, for several decades. Their action is at the level of ribosomes where they interfere with protein metabolism. The later introduction of broad-spectrum cephalosporins and fluoroquinolones offered an apparently safer alternative to the aminoglycosides and their use declined. However, aminoglycosides appear to be much less likely to promote *C. difficile*, and they are experiencing a renaissance as a treatment for serious infections. Once-daily administration is now generally used, being as effective and with less risk of toxicity than traditional three times daily regimens. Treatment duration should be limited and not prolonged when other antibiotics would suffice.

Duration of Antibiotic Therapy in Acute Simple UTI

Compliance with therapy may be improved by using shorter courses of antimicrobial therapy or ideally by using a single-dose regimen. However, a large number of studies have assessed the use of single-dose therapy and found it not to be as effective as a short-term (3-day) regimen [105]. There is also a risk of selecting resistance in the surviving bacteria. There is no evidence to show that protracted courses are more effective in uncomplicated lower UTIs in adult women [106].

PREVENTION OF BACTERIAL CYSTITIS

Prophylaxis

In women complaining of recurrent infections related to sexual intercourse, postcoital voiding should be encouraged. Appropriate advice regarding bladder emptying such as double voiding may also help those with voiding difficulties. Meticulous attention to perineal hygiene, including bathing the perineum with a salt-water solution at the first symptoms of infection and postcoitally in affected women, is a useful self-help regime as published by Kilmartin [107].

Antibiotic Prophylaxis

Antibiotics are effective when used as a prophylaxis for recurrent UTIs [108] in premenopausal women who do not respond to the aforementioned measures and in postmenopausal women who do not respond to topical estrogen (described in the succeeding text). A long-term low-dose prophylaxis with nitrofurantoin or trimethoprim for 6 months may be considered. Patients are less likely to stop nitrofurantoin prematurely due to side effects if the macrocrystalline formation (Macrodantin) is used rather than the microcrystalline form [102]. Nitrofurantoin should not be used for more than 12 months continuously due to the small risk of pulmonary fibrosis (usually in those with renal insufficiency) [101]. Self-diagnosis and self-treatment by the patient have been proven as efficacious as continuous therapy in both younger women [109] and the elderly [110]. Adverse effects were significantly lower, suggesting it may be a good alternative as well as reducing antibiotic use and costs. Postcoital therapy has been proven to be as effective as daily long-term medication [111]. The choice of antibiotic depends on the bacteria found on culture and their patterns of resistance, as well as the patient's history and known allergies. Side effects can be a disadvantage. However, with the ever-rising bacterial resistance to antibiotics, other methods in treating recurrent UTIs are becoming increasingly important.

Estrogen Therapy in Postmenopausal Women

Endogenous estrogen levels drop after menopause, resulting in a decrease in lactobacilli colonization of the vagina, a rise in vaginal pH, and a subsequent increase in colonization with uropathogenic bacteria. Estrogens encourage the growth of *Lactobacilli*, lowering the pH to the desired level of 4.5, which inhibits bacterial growth [112]. Additionally, it induces the expression of antimicrobial peptides and promotes tighter intercellular connection, prohibiting bacteria from reaching cells [112]. Moreover, estrogen also possibly helps decrease postvoid residual due to improved contractility of the bladder, therefore reducing another risk of cystitis. Estrogens can be administered either locally (cream, pessaries, estradiol-releasing rings) or orally. Although oral estrogens do lower the vaginal pH, they have not been effective in preventing the recurrence of UTIs [64]. Administering estrogens locally, by applying estriol cream or inserting an estrogen pessary, significantly decreases the vaginal pH as well as reducing recurrent UTIs. A randomized controlled trial by Raz et al. compared estriol cream to placebo cream with a follow-up of 8 months [113]. There was a significant reduction in UTI episodes in the group given estriol cream (0.5 versus 5.9 episodes a year, $p < 0.001$). A higher percentage of women also remained UTI-free. After estriol treatment, the colonization of *Enterobacteriaceae* halved and was replaced by *Lactobacilli*, absent prior to treatment. A trial comparing estradiol-releasing silicone ring (Estring) to no treatment demonstrated a greater percentage remaining UTI-free in those in the treatment group (45% versus 20%, $p = 0.08$). Estring was also associated with a reduction of recurrences and a prolonged interval between infections [114]. Overall, the evidence supports the use of local estrogen in postmenopausal women with recurrent UTIs and should be offered.

Methenamine Salts

Methenamine hippurate (Hiprex) is the most common form of methenamine salts used to prevent UTIs. It produces formaldehyde from hexamine, which has bacteriostatic effects. However, studies have demonstrated that a urinary pH below 5.5 is required to generate bacteriostatic levels of free formaldehyde from methenamine hippurate [115]. Therefore, certain bacteria that increase the pH of urine, such as *Proteus* and possibly *Pseudomonas*, may not be prevented. Ascorbic acid can be used in high doses (1–4 g) to help lower the urinary pH. Overall, methenamine hippurate is well tolerated and it is not associated with antibiotic resistance.

A Cochrane review published in 2012 included 13 studies of variable quality [116]. Subgroup analyses demonstrated possible benefits in patients without renal tract abnormalities and a significant reduction in symptomatic UTIs was seen when treating these patients in the short term (7 days or less). However, the authors recommend further well-designed RCTs due to the mixed quality of the included studies.

Cranberry

Cranberry (*Vaccinium macrocarpon* Ait) products such as tablets and juice have long been used to reduce cystitis. There is increased interest in research regarding cranberry efficacy, because of the emergence of antibiotic-resistant strains of bacteria.

Recent studies found two types of chemical compounds in cranberries that prevent bacterial adhesion, the monosaccharide fructose and proanthocyanidins (PACs) [117]. In vitro studies have demonstrated that fructose inhibits adhesion of (mannose-sensitive) type 1 fimbriae to uroepithelial cells, although this effect has not yet been clinically proven. PACS, especially the A-type linkages, are thought to be of significant importance in preventing P-fimbriated *E. coli* adhesion to uroepithelial cells [117,118].

Although cranberry has been shown to prevent adhesion of UPEC to urothelial cells in vitro, clinical trials have shown varying results. Stothers et al. randomized 150 women to treatment with cranberry juice, cranberry tablets, or placebo [119]. Both cranberry products significantly decreased the number of women suffering from at least 1 UTI a year (20% and 18%, respectively) compared to placebo (32%). The Cochrane review in 2012 [120] concluded that cranberries did not significantly reduce the risk of recurrent symptomatic UTIs, in contrast to their previous publication. However, the studies were of limited quality, as the type of product and quantity of active cranberry ingredient used differed greatly between the studies or were not even noted. A second large meta-analysis found that there was some evidence that cranberry reduces symptomatic UTIs, especially in women with recurrent UTIs, and recommended its use [121].

In vitro studies have shown that there is a clear dose dependency [118]. Although both 36 and 72 mg of PAC equivalents per day are effective in reducing anti-adherence properties of *E. coli*, 72 mg has greater efficacy at 24 hours. Therefore, if patients are using cranberry products to reduce recurrent UTIs, they should be advised to use products containing at least 36 mg PACs. It may be more beneficial to consume two doses of 36 mg, in the morning and evening. “Cysticlean R” has an extremely high PAC content (118 mg) and is the most commonly used in the United Kingdom. More human trials are required to confirm these effects in preventing UTIs.

D-Mannose Oral Therapy

Because the FimH pili of *E. coli* bind to urothelial cell receptors containing mannose, small clinical trials have shown benefit for patients who ingest D-mannose, a large molecular weight sugar that attracts *E. coli* to the molecule and facilitates binding to superficial urothelial cells that regularly desquamate and are swept out into the urine (see www.dmannose.co.uk). Randomized trials of this therapy are not yet available.

Probiotics

Probiotics are defined by the World Health Organization as “live microorganisms, which when administered in adequate amounts confer a health benefit to the host” [122]. Recent work on their effects to replete the colonization of lactobacilli has shown promising results. Stapleton et al. randomized 100 women with recurrent UTIs to *Lactobacillus crispatus* vaginal suppositories (Lactin-V) or placebo after conventional antibiotic treatment. In the treatment group, prolonged colonization with *L. crispatus* was demonstrated, and the incidence of recurrent UTI was reduced by almost half (15% in the Lactin-V group versus 27% in the placebo group, $p = 0.01$) [123]. Another study comparing *Lactobacilli* (*L. rhamnosus* and *L. reuteri*) to trimethoprim prophylaxis did not reach noninferiority criteria (recurrence in 79% versus 69%, respectively). However, there was a striking increase in antibiotic-resistant *E. coli* after trimethoprim from 20%–40% to 80%–95% [124].

Immunoprophylaxis

Various types of immunoprophylaxis have been studied using bacterial extracts. Oral immunostimulant OM-89 significantly decreased the incidence of UTIs (by approximately 50%) when compared to placebo. The percentage of patients that developed side effects was comparable to the nontreatment groups [115]. Vaginally applied vaccines have also been developed, but the success has been limited in human pilot studies. Further research in this area with larger randomized controlled trials is needed [115].

EMERGING ASPECTS OF BACTERIAL CYSTITIS IN UROGYNECOLOGY: THE WOMAN WITH REFRACTORY DETRUSOR OVERACTIVITY

Bacterial Cystitis and Overactive Bladder

Classically, bacterial cystitis results in inflammation of the lower urinary tract, which causes dysuria and foul-smelling, discolored urine. The notion that bacterial cystitis may also be associated with incontinence is not generally discussed in the infectious disease literature, although most continence clinicians are aware of this problem. For the last 40 years, urodynamic DO has been considered a separate and independent condition. However, doctors have traditionally excluded bacterial cystitis (by dipstick test or urine culture) before commencing urodynamic tests [125].

Older urological publications did propose a link between "uninhibited neurogenic bladder" [126] or urge incontinence [127] and recurrent urinary infection. The suggested mechanism was either ischemia in the bladder wall [126] or an increased sensory input from the inflamed mucosa [128,129]. In 2000 and 2004, two large urodynamic studies (n = 862 and 1017) did show that women with newly diagnosed DO had classical cystitis (8%–10%) compared to 1%–4% in those without DO [125,130,131].

In the last 10 years, urogynecologists have shifted away from the term "urodynamically proven DO" and moved toward the term "overactive bladder syndrome," which by definition excludes bacterial cystitis. Despite this move away from diagnostic urodynamic testing, clinicians became increasingly aware of the problem of refractory OAB [132]. The notion that at least one third of these refractory women were found to have some degree of bacterial cystitis (as evidenced by bacteriuria with or without pyuria or histological inflammation on biopsies) has been reported by four research groups in the last 4 years [2,125,133–142].

In a study in Sydney, 50 women with refractory idiopathic DO over 2 years were asked to provide an MSU whenever their OAB symptoms worsened. None of these patients had dysuria or foul-smelling urine [142]. The results showed that 39% had bacteriuria, versus 6% of the controls. As regards only "low-count bacteriuria," 17 of the refractory idiopathic DO (IDO) group versus 2% of the control group showed this finding [125].

The same authors consequently studied CSUs taken at urodynamic testing, from patients with newly diagnosed IDO versus other types of incontinence (n = 151), compared with CSU taken from 62 continent women with no OAB symptoms [143]. This revealed an odds ratio of 4.06 for any bacteriuria in the incontinent group versus continent controls, in particular patients with pure DO (odds ratio 4.4). Another study of catheter specimens of patients with refractory IDO revealed bacteriuria $>10^3$ CFU/mL in 27% of these refractory patients [125,144].

Simultaneously, another group in London was investigating the problem of refractory DO by evaluating bladder biopsies. Of the 106 women studied, histopathological analysis revealed chronic cystitis in 96 women and follicular cystitis in 3 women (93% combined) [135]. The same group went on to evaluate microbiological culture of homogenized bladder biopsies from 156 women with refractory OAB, of whom 38% had a history of recurrent bacterial cystitis. Although most patients had sterile CSU specimens on the day, a wide range of microbes were cultured, including some fastidious organisms, from bladder biopsies in 52% of patients [125,145].

At the same time, a further group in London was studying a broader group of patients with new-onset urgency/nocturia and other lower urinary tract diseases (LUTDs), without dysuria. A study comparing "classical cystitis" to "low-count bacteriuria" cystitis in 470 CSU specimens revealed cystitis rates of 15% versus 29%, respectively [97]. The authors concluded that the use of the "classical" threshold for UTI diagnosis in patients with nondysuric LUTD was of concern. They subsequently investigated women with chronic "urgency" associated with other LUTDs, compared to controls. CSU specimens revealed a wide array of organisms causing bacteriuria at the 10^2 diagnostic threshold in the LUTD group [125,138].

A study on women with urgency incontinence undergoing treatment with onabotulinum toxin A injection revealed increased symptoms in those in which bacterial DNA was detected using quantitative polymerase chain reaction (qPCR) [146]. Although this did not affect the outcome of the treatment, those positive for bacterial DNA were more likely to develop a UTI posttreatment.

Moreover, additional work has shown that bacteria may chronically reside in urothelial cells of the bladder, therefore forming IBCs resulting in low-count bacterial cystitis and possibly contributing to refractory OAB and recurrent UTI due to reinfection [58,147,148]. The development of drugs capable of penetrating the membrane of infected cells is needed, so as to eradicate these bacterial colonies [125].

In the last 5 years, there have been two studies of antibiotic therapy in patients with OAB. In 2011, researchers from University College treated 147 patients with OAB with nitrofurantoin or cephalexin (combined with antimuscarinic drugs and bladder training). For comparison, 212 patients with OAB, but without pyuria, who had received the same standard therapy previously, were studied. The prevalence of traditional cystitis on MSU was 25% versus 12%, respectively. The response to treatment (voids per 24 hours) was significantly greater in the antibiotic group versus standard treatment group ($p < 0.001$) [136]. Few microbiological details of patients' urine samples were provided. Arising from the bladder biopsy study of Digesu et al. [135], the same authors treated 39 women who had refractory idiopathic DO and biopsy evidence of chronic cystitis, with a 6-week course of rotating antibiotics (ciprofloxacin, doxycycline, cephalexin). This treatment yielded a significant reduction in voiding frequency, urgency scores, quality of life tests (all $p < 0.05$), as well as reduction in urinary nerve growth factor [141]. Again, no microbiological details regarding the persistence or cure of bacterial cystitis were given in this open prospective study [125]. Currently, a placebo-controlled phase II study is in progress in Australia (ACTRN12613000285752).

CONCLUSION

- Bacterial cystitis is common in women of all ages and is a major problem in urogynecology.
- In contrast to previous beliefs, urine is commonly not sterile.
- Rigid adherence to Kass's criteria for classical cystitis and the use of standard urine culture techniques lead to significant underdiagnosis of UTI, particularly in women with refractory OAB.
- In the last two decades, multiresistant uropathogens are becoming increasingly prevalent so that clinicians must be ever more vigilant in their choice of antimicrobial therapy.

ACKNOWLEDGMENTS

Sincere thanks to the previous authors of this chapter, James Grey and Dudley Robinson, whose work has been incorporated into this revised edition. We also acknowledge Colin Walsh for his research on the association between overactive bladder symptoms and low-count bacteriuria, as well as Thomas Hannan for the studies on *E. coli* included in this chapter. We thank Professor Peter Taylor, clinical microbiologist, for his input into the pathogenesis and antimicrobial sections.

57 Vaginitis

J.D. Sobel

INTRODUCTION

Vulvovaginal symptoms are extremely common and are a major reason many women seek healthcare [1]. Vaginal symptoms include an abnormal discharge, which may be caused by either vaginal or cervical infection or may be due to numerous noninfectious causes. Other common symptoms include vulvovaginal pruritus, irritation, discomfort, burning, genital malodor, and variable discomfort or pain during or following intercourse. Women may perceive a change in normal vaginal discharge reflecting a qualitative or quantitative alteration. Clinicians should not trivialize and dismiss this complaint [2]. Instead, they should thoroughly evaluate the women's symptoms by clinical examination and routine laboratory tests such as pH, microscopy, and occasionally culture. Some patients have other comorbid disorders such as atopy and common dermatoses, e.g., eczema or psoriasis, which may be relevant to vulvar symptoms. While bacterial vaginosis (BV), vulvovaginal candidiasis (VVC), and trichomonas vaginitis are the most common infectious entities causing vulvovaginitis, it should be emphasized that vulvovaginal symptoms are more frequently the result of noninfectious etiology. Clinicians should cease to restrict consideration of differential diagnosis of vulvovaginal symptoms, considering only cervical or vaginal infection as the cause of symptomatology. Clinicians are required to reach a specific diagnosis and avoid empiricism. Prescribing empirical measures including the use of steroids when no diagnosis is available should be avoided. Syndromic medicine is not an acceptable standard of care in industrialized countries (Table 57.1).

CANDIDA VULVOVAGINITIS

Epidemiology

VVC is extremely common in adolescents and adults[3]. Of female university students, 50% will have at least one physician diagnosed episode by the age of 25 and as many as 75% of premenopausal women report having had at least one episode and 45% of women have two or more episodes [4]. VVC is less common in postmenopausal women unless they are taking estrogen therapy. It is estimated that 6%–8% of adult women suffer from recurrent *Candida* vaginitis (RVVC), which translates into millions of women worldwide [3,4]. RVVC is defined as four or more episodes in a given year. Epidemiological data are incomplete, however, for several reasons: (1) Diagnosis of VVC is nonreportable and therefore prevalence estimates rely mainly upon self-reported histories of diagnosis by a physician. (2) *Candida* infection is routinely diagnosed without the benefit of microscopy or culture, and as many as one-half of the women given this diagnosis may have other conditions. (3) Finally, the widespread use of over-the-counter (OTC) antifungal drugs makes epidemiological studies difficult to perform in most countries. Self-diagnosis and therefore self-therapy is prevalent.

Pathogenesis

Candida organisms probably gain access to the vagina via migration across the perianal area from the rectum. However, once colonization occurs, long-term colonization frequently persists for months and years. Following *Candida* colonization, the organisms persist in the presence of the normal protective vaginal flora without causing symptoms until additional precipitating factors alter the delicate relationship between the *Candida* microorganisms and the vaginal microbiota as well as protective host defenses. A large number of underlying risk factors contribute to both colonization as well was symptomatic disease (Figure 57.1).

Microbiology

Candida albicans is responsible for 90% or more of episodes of VVC [3]. The remainder of the attacks are caused by non-*albicans Candida* species, which included *C. parapsilosis*, *C. glabrata*, *C. tropicalis*, and a variety of rare *Candida* species, an occasional non-*Candida* yeast *Saccharomyces* species. Some investigators have reported an increased frequency of the non-*albicans Candida* species particularly *glabrata*, but this has not been confirmed [5]. The non-*albicans Candida* species appear to be less virulent both in patients as well as in animal models used to study pathogenesis. Nevertheless, these species are still capable of causing symptomatic vaginitis, although their causal role needs to be established in each given patient. Accordingly, all *Candida* species produce similar vulvovaginal symptoms, although the severity of symptoms appears to be milder with *C. parapsilosis* and *C. glabrata* as compared to *C. albicans*.

Risk Factors

Sporadic attacks of VVC frequently occur without identifiable precipitating factors. Nevertheless, a number of factors do predispose to symptomatic infection:

- One-quarter to one-third of women are prone to VVC during or after taking broad spectrum antibiotics. No antibiotics either systemic or local are immune from this complication. The mechanism whereby antibiotics induce *Candida* vaginitis has not been fully established. Previously, it was thought that antibiotics inhibit bacterial flora primarily in the gastrointestinal tract or possibly within the vagina allowing the overgrowth of potential pathogens such as *Candida*. However, confirmation of this hypothesis is not available. Administration of lactobacillus (oral or vaginal) probiotics during or after taking antibiotic therapy does not prevent post-antibiotic VVC [6].

Table 57.1 Vaginal Syndromes and Their Etiologies

Type	**Etiology**
Infectious	
Bacterial vaginosis	Mixed *Gardnerella vaginalis*, anaerobes (*Prevotella, Porphyromonas, Bacteroides, Fusobacterium, Peptostreptococcus, Mobiluncus, Megasphaera, Eggerthella, Leptotrichia*, members of the *Clostridiales* order), and genital mycoplasmas
Candida vulvovaginitis	90% *Candida albicans*, 10% *non-albicans Candida* species; rarely other fungi
Trichomoniasis	*Trichomonas vaginalis*
Rare bacterial	Group A *Streptococcus*
Noninfectious	
Atrophic vaginitis	Estrogen-deficient states (postmenopausal, postpartum, post-antiestrogen therapy)
Contact vulvovaginitis	Contact dermatitis (hypersensitivity)
Chemical irritant vaginitis	Soaps, detergents, topical antimycotics
Allergic vaginitis	Allergens
Desquamative inflammatory vaginitis (DIV)	Unknown (bacterial? immune mechanism?)
Erosive lichen planus	Immune mechanisms
Collagen vascular diseases (SLE)	Vasculitis
Pemphigus and pemphigoid syndromes	Immune mechanisms

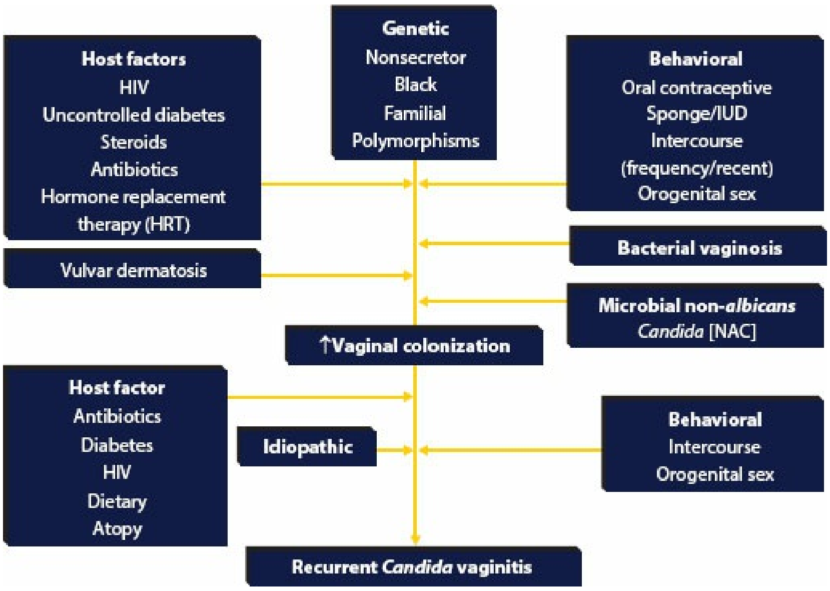

Figure 57.1 Pathogenesis of recurrent *Candida vaginitis* (RVVC).

- *Increased estrogen levels*. VVC is rare before puberty and tends to be less frequent in the postmenopausal women not taking any form of exogenous estrogen. Similarly, symptoms tend to flare in the premenstrual period on a cyclical basis. VVC appears to be more common in the setting of increased estrogen levels such as with oral contraceptives, especially when estrogen dose is high, pregnancy, and premenopausal estrogen therapy, especially with topical use of estrogen [3].
- *Diabetes mellitus*. Women with diabetes, especially those with poor glycemic control, are more prone to VVC. In particular, women with Type 2 diabetes appear to be prone to *C. glabrata* infections; nevertheless, most women with RVVC do not suffer from diabetes including prediabetes. Routine tests for diabetes are not indicated in women prone to VVC.
- *Immunosuppression. Candida* infections are more common in immunosuppressed patients especially those taking corticosteroids or with uncontrolled HIV infection [7].
- *Contraceptive devices*. Vaginal sponges, diaphragms, and IUDs have been associated with VVC. Spermicides are not thought to increase VVC.
- *Genetic susceptibility*. Although a genetic factor was suspected for many years, evidence confirming this relationship was not available until recently [8]. Earlier, suspicions were based on a family history and blood group, including blood secretor status. It is likely that more than one genetic factor is complicit in the pathogenesis of VVC. Genetic factors may be important in colonization, as well as in determining the immune response to the presence of proliferating organisms within the vagina [7,8]. Accordingly, VVC has been reported with decreased in vivo concentrations of mannose-binding lectin (MBL) and increased concentrations of IL-4 [9,10]. Two specific gene polymorphism variance in the MBL and IL-4 genes can account for this finding in some high-risk women, but their relevance remains controversial. The prevalence of a variant MBL gene is higher in women with RVVC than in controls without candidiasis [10]. Recognition of *C. albicans* by the innate hose defense system is mediated by pattern recognition from the toll-like receptor (TLR) and lectin-like receptor families. Mannans from the *Candida* cell wall are recognized by the mannose receptor, and TLR4 and TLR2 recognize phospholipomannan and collaborate with protective cytokine production [8].
- *Behavioral factors*. Although VVC is not considered a sexually transmitted disease because it occurs in celibate women and since *Candida* is considered part of the normal vaginal flora, this does not mean that the sexual transmission of *Candida* microorganisms does not occur or that VVC is not associated with sexual activity. Accordingly, one observes an increase in the frequency of VVC at the time that most women begin regular sexual activity [11]. Male partners of infected women are more likely to have penile colonization than partners of uninfected women, and usually with the same strain as indicated by strain typing [12].

- There is no high-quality evidence showing the link between VVC and hygienic habits or in using tight or synthetic clothing.
- *HIV infection*. VVC occurs with higher incidence and greater persistence but not greater severity among HIV-infected women. A significantly increased rate of symptomatic infection is confined only to HIV-infected women with very low CD4 counts and very high viral load, a population likely to manifest other AIDS manifestations. HIV testing of women, only for the indication of recurrent VVC, is not justified given that RVVC is a common condition in women without HIV infection and the majority of cases occur in HIV-uninfected women. Only women with risk factors for acquisition of HIV should be counseled and offered screening. The microbiology of recurrent VVC in HIV-infected women is the same as HIV-negative women [3].
- *Candida* colonization of the vagina in asymptomatic women may persist for prolonged periods of time until precipitating exogenous factors trigger a change in the balance between seed and soil. Triggering is most often the result of changes in the host, in which naturally occurring anti-*Candida* vaginal defensive mechanisms diminish or fail. *Candida* proliferation follows with increase in numbers of organisms and expression of virulence factors including hyphal formation and elaboration of proteases. The development of symptoms and signs of vulvovaginal inflammation, however, usually requires the involvement of the host adaptive immune response reacting to the proliferating organisms [7]. It is this latter response that is critical for the development of symptomatic VVC and may be seen as an unnecessary by-product of the host defense system reacting to the organisms.

Clinical Features

Vulvar pruritus is the dominant feature of VVC. Women may also complain of dysuria, often described as external rather than internal, irritation, soreness, and dyspareunia. There is little or no discharge and that when present is typically white and clumpy. Physical examination reveals erythema of the vulva and vaginal mucosa and vulvar edema. The discharge is typically described as clumpy and cottage cheese-like. However, it may also be thin and watery, indistinguishable from the discharge of other forms of vaginitis. Some patients, particularly those with *C. glabrata* infection, have little discharge with only erythema on vaginal examination. The vulva is invariably involved and fissures may be present. It is important to recognize that in contrast to BV, *Candida* infection involves both vulva and vagina.

Diagnosis

The vaginal pH is typically 4–4.5, which distinguishes VVC from trichomoniasis or BV. The clinical diagnosis should be confirmed by finding the organism on saline wet mount microscopy and by adding 10% KOH, which facilitates the microscopic recognition of the yeast and hyphal morphotype. Unfortunately, microscopy may be negative in 50% of patients with confirmed VVC. Empiric therapy is often considered with typical clinical findings, normal vaginal pH, and no other pathogens visible on microscopy. However, with an unconfirmed microscopy-based diagnosis, a culture should be obtained. Often empiric therapy can be delayed until the results of additional tests are available. Cultures provide confirmation of the diagnosis within 48–72 hours and also reveal the species of the organism, which facilitates the selection of the appropriate antifungal agent. Culture should always be obtained in patients with persistent or recurrent symptoms because many of these women have non-*albicans Candida* infections with reduced susceptibility to azoles. In the presence of positive microscopy and a normal pH, a routine culture is not essential, but is mandatory for microscopy-negative patients.

Low-risk commercial tests are now available as an alternative to culture. These include a DNA probe with hybridization, which is particularly useful and should provide results within several hours to confirm the initial clinical diagnosis. PCR testing is widely available through commercial laboratories and is a highly sensitive method that provides *Candida* speciation when positive. The cost efficacy of the PCR technology has not been evaluated and may take 48–72 hours for results, similar to microbial culture. Although PCR offers a more sensitive method of diagnosis, the clinical relevance of this increased sensitivity is unknown.

The mere demonstration of *Candida* presence by any of the aforementioned diagnostic methods in no way confirms the pathogenic role of *Candida* in the specific patient or clinical syndrome. This is because *Candida* is found colonizing 15%–20% asymptomatic healthy women. Accordingly, the presence of *Candida* does not imply culpability. Determination of causation of symptoms requires exclusion of other pathogens plus other noninfectious causes. There are no other infectious causes responsible for vulvovaginal symptoms at normal pH 4.0–4.5.

Differential Diagnosis

Other conditions should be considered in the differential diagnosis of symptomatic women with normal vaginal pH, and these include allergic and chemical reactions, hypersensitivity reactions, and contact dermatitis. These conditions are extremely common and frequently will cause symptoms in the presence or absence of *Candida*. If the vaginal pH exceed 4.5 or excessive polymorphonuclear leukocytes (PMNs) are present, mixed infections with BV or trichomoniasis may be present. Based on the aforementioned criteria, there should be no difficulty separating BV from *Candida* vaginitis. Self-diagnosis of VVC is frequently inaccurate. Similarly, diagnosis of *Candida* vaginitis by telephone is unreliable and is to be condemned.

Treatment

Treatment is indicated for relief of vulvovaginal symptoms. There is no indication to treat asymptomatic colonization in culture-positive women. A number of highly effective oral and intravaginal antifungals are available (Table 57.2). Nystatin is the least effective with cure rates in the 70%–75% range. The remaining antifungals have published efficacies in the 80%–88% range. Of the intravaginal imidazoles, clotrimazole, miconazole, butoconazole, and tioconazoles are available over the counter (OTC in the United States), while terconazole is available only by prescription. All these topical agents are highly effective and are prescribed as single-day to 7-day regimens. There appears to be no superiority of one regimen over another [13]. Topical regimens are well tolerated with few adverse effects, although burning may occasionally occur. Mild disease is best treated with shorter dose regimens.

Table 57.2 Therapy for Vaginal Candidiasis

Drug	**Topical agents and formulation**	**Dosage regimen**
Butoconazole[a]	2% cream	5 g × 3 days
Clotrimazole[a]	1% cream	5 g × 7–14 days
	2% cream	5 g × 3 days
	100 mg vag. tab.	1 tab. × 7 days
	100 mg vag. tab	2 tab. × 3 days
	500 mg vag. tab.	1 tab. single dose
Miconazole[a]	2% cream	5 g × 7 days
	4% cream	5 g × 3 days
	100 mg vag. supp.	1 supp. × 7 days
	200 mg vag. supp.	1 supp. × 3 days
	1200 mg vag. supp.	1 supp. single dose
Econazole	150 mg vag. tab	1 tab. × 3 days
Fenticonazole	2% cream	5 g × 7 days
Tioconazole[a]	2% cream	5 g × 7 days
	6.5% ointment	5 g single dose
Terconazole	0.4% cream	5 g × 7 days
	0.8% cream	5 g × 3 days
	80 mg vag. supp.	80 mg × 3 days
Nystatin	100,000 U vag. tab.	1 tab. × 14 days
	Oral Agents	
Ketoconazole	400 mg bid	× 5 days
Itraconazole	200 mg bid	× 1 days
	200 mg	× 3 days

Fluconazole	150 mg	Single dose

Abbreviations:vag., vaginal; tab., tablets; supp., suppository

[a] OTC in the United States

Oral agents are available in the United States for the treatment of *Candida* vaginitis and include fluconazole, which is supplied as a single 150 mg oral tablet, itraconazole, and ketoconazole. Only fluconazole is FDA approved for VVC treatment [14,15].

Selection of the appropriate antifungal agent and the duration of therapy has been facilitated by the complicated VVC and uncomplicated VVC classification. Most women (uncomplicated VVC), being healthy, host with mild to moderate, infrequent episodes of vaginitis due to *C. albicans*. Under these circumstances, patients respond to all azoles, topical or systemic, with a success rate in excess rate of 90% regardless of duration of therapy (Table 57.3).

In contrast, women with complicated VVC respond less well to short-course azole therapy. Accordingly, a compromised host women with severe vaginitis should receive more prolonged, conventional antimycotic therapy usually requiring up to 7 days of treatment [13–16]. Treatment of women infected with non-*albicans Candida* species remains problematic. *C. krusei* infection is fortunately extremely rare and resistant to fluconazole but responds rapidly to other azoles. Vaginitis due to *C. glabrata* is however refractory to all forms of azole therapy with 50% success. Somewhat improved results are achieved with vaginal boric acid and with 60%–70% eradication rates [17,18]. The best results follow vaginal therapy with 17% flucytosine cream. The latter has to be compounded, is not available commercially, and is extremely expensive. More important than selecting an antifungal agent is deciding whether to treat vulvovaginal symptoms in the presence of culture-positive *C. glabrata*. The mere finding of *C. glabrata* does not imply complicity in the pathogenesis of the clinical syndrome. More often than not, *C. glabrata* is an innocent bystander and intensive treatment regimens directed at *C. glabrata* frequently fail. Moreover, even when successful, organism elimination is not accompanied by concomitant relief or eradication of symptoms. In the experience of some investigators, less than 25% of symptomatic *C. glabrata* positive patients' symptoms can be attributed to *C. glabrata* isolated. Nevertheless, when no other explanation for symptoms is available, a trial of therapy is clearly justified, but clinicians should not trivialize the complex relationship between this yeast and vulvovaginal symptoms.

Table 57.3 Classification of Vulvovaginal Candidiasis

Uncomplicated	**Complicated**

Abbreviations:VVC, vulvovaginal candidiasis

Treatment of Recurrent Vulvovaginal Candidiasis

As described earlier, RVVC occurs in 5%–8% of the population in women during their reproductive period [3]. It is likely that genetic factors are operative in the overwhelming majority of such patients. Nevertheless, secondary precipitating mechanisms are frequently present and vary from patient to patient. Thus, while all patients share an underlying genetic predisposition, triggers to symptomatic episodes vary considerably. Resistance of microorganisms to azole drugs is a rare cause of RVVC.

Before embarking on any treatment protocol, the diagnosis must be confirmed by the presence of culture, which includes organism speciation. Fungal susceptibility tests are not routinely indicated unless drug breakthrough infection or refractory disease occurs with appropriate azole therapy. Every effort should be made to control trigger mechanisms including the use of antibiotics, control of diabetes, and local predisposing factors such as concomitant vulvar dermatosis. Once these factors have been excluded or treated, an induction regimen with an antimycotic followed by a long-term suppressive maintenance regimen is indicated. While this can be accomplished with topical regimens, because of the duration and frequency of therapy, oral therapy is more convenient and offers a more realistic solution.

It should be emphasized that the therapy selected is aimed at controlling symptomatic episodes rather than guaranteeing that cure will be achieved. The use of long-term suppressive maintenance regimens has been confirmed in several prospective controlled studies [19,20]. Accordingly, after an induction regimen of fluconazole 150 mg given every 72 hours for 3 doses, a weekly maintenance regimen of fluconazole 150 mg once weekly is suggested. Complete resolution of symptoms follows within a matter of weeks, and the patients remain asymptomatic for the duration of therapy, which is recommended for 6 months. During this period, the patient invariably remains culture negative and asymptomatic. Following discontinuation of therapy after 6 months, approximately 50% of the patients rapidly become recolonized and develop recurrent symptoms of VVC. However, 50% of patients will return to an attack-free life with risks similar to low-risk women. Should symptomatic recurrence rapidly follow discontinuation of therapy, repeat reinduction and maintenance therapy is recommended this time for at least 12 months. Frequently, even longer prolonged maintenance regimens are recommended and required.

BACTERIAL VAGINOSIS

Epidemiology

BV is the most common cause of vaginitis in women of childbearing age. It has been diagnosed in 17%–19% of women seeking gynecological care in family practice or student health-care settings [1]. The worldwide prevalence ranges from 11% to 48% of women of reproductive age, with variation according to population studied [21]. The prevalence increases considerably in symptomatic women attending STD clinics, reaching 24%–37%. BV has been observed in 16%–29% of pregnant women. *Gardnerella vaginalis* has been found in 10%–31% of virgin adolescent girls but is found significantly more frequently among sexually active women, reaching a prevalence of 50%–60% in some at-risk populations.

Evaluation of epidemiological factors has revealed a few clues of the cause of BV. Use of an intrauterine device and douching was found to be more common in women with BV. BV is significantly more common among black and sexually active women including lesbians.

Pathogenesis and Pathology

BV is not due to a single organism and is the result of massive overgrowth of mixed complex flora or microbiota, including peptostreptococci, *Bacteriodes* spp., *G. vaginalis*, *Mobiluncus* spp., genital mycoplasma, and a variety of recently described anaerobes [22]. There is little inflammation, and the disorder represents a disturbance of the vaginal microbial ecosystem rather than a true infection of tissues. The overgrowth of mixed flora is associated with a loss of the normal *Lactobacillus* sp.–dominated vaginal flora [21]. No single bacterial species is responsible for BV. Experimental studies in human volunteers and studies in animals indicate that inoculation of the vagina with individual species of bacteria associated with BV (e.g. *G. vaginalis*) rarely results in BV. In support of the role of sexual transmission is the higher prevalence of BV among sexually active young women than among sexually inexperienced women, and the observation that BV-associated microorganisms are more frequently isolated from the urethras of male partners of females with BV.

The cause of the overgrowth of anaerobes, *G. vaginalis*, *Mycoplasma*, and *Mobiluncus* spp., is unknown. Theories include increased substrate availability, increased pH, and loss of the restraining effects of the predominant *Lactobacillus* sp. flora. It has been reported that normal women are predominantly colonized by hydrogen peroxide–producing strains of lactobacilli, whereas women with BV have reduced population numbers of lactobacilli, and the species present lack the ability to produce hydrogen peroxide [21]. The hydrogen peroxide produced by lactobacilli may inhibit the pathogens associated with BV.

Accompanying the bacterial overgrowth in BV is the increased production of amines by anaerobes, facilitated by microbial decarboxylases. Volatile amines in the presence of increased vaginal pH produce the typical fishy odor, which is also produced when 10% potassium hydroxide is added to vaginal secretions. Trimethylamine is the dominant abnormal amine in BV. It is likely that bacterial polyamines together with the organic acids found in the vagina in BV (acetic and succinic acid) are cytotoxic, resulting in exfoliation of vaginal epithelial cells and creating the vaginal discharge. *Gardnerella vaginalis* attaches avidly to exfoliated epithelial cells, especially at the alkaline pH found in BV. The adherence of *Gardnerella* organisms results in the formation of the pathognomonic clue cells. Using broad-range DNA probes, new molecular methods have identified at least 35 new bacterial phylotypes (species), previously uncultivatable in women with BV including *Atopobium vaginae* and *Clostridial species* BVAB I, II, and III offering new insights into pathogenesis [22,23].

Prevention

Because the pathogenesis of BV is obscure, preventive measures have not been forthcoming. Although not proven to be sexually transmitted, barrier contraception may reduce occurrence and avoiding douching is recommended.

Clinical Features

As many as 50% of women with BV may be asymptomatic. An abnormal malodorous vaginal discharge, often described as fishy, that is infrequently profuse and often appears after unprotected coitus is usually described. Pruritus, dysuria, and dyspareunia are rare. Examination reveals a nonviscous, grayish-white adherent discharge.

BV has been incorrectly considered to be largely of nuisance value only. There is now considerable evidence of serious obstetric and gynecological complications of BV, including asymptomatic BV diagnosed by Gram stain. Obstetric complications include chorioamnionitis, preterm labor, prematurity, and postpartum fever [24]. Gynecological sequelae are postabortion fever, posthysterectomy fever, cuff infection, and chronic mast cell endometritis. A more recent association is reported between untreated BV and cervical inflammation and low-grade dysplasia [25]. BV is a risk factor for HIV acquisition and transmission [26]. BV is also a risk factor for acquisition of HSV-2, gonorrhea, and chlamydial infection [27].

Diagnosis

Signs and symptoms are unreliable in the diagnosis of BV. The clinical diagnosis can reliably be made in the presence of at least three of the following objective criteria:

1. Adherent, white, nonfloccular homogeneous discharge
2. Positive amine test, with release of fishy odor on addition of 10% potassium hydroxide to vaginal secretions
3. Vaginal pH > 4.5
4. Presence of clue cells on light microscopy

These Amsel features are simple and reliable, and tests for them are easy to perform. The presence of clue cells is the single most reliable predictor of BV. Clue cells are exfoliated vaginal squamous epithelial cells covered with *G. vaginalis*, giving the cells a granular or stippled appearance with characteristic loss of clear cell borders.

The offensive fishy odor may be apparent during the physical examination or may become apparent only during the amine test. Gram strain of vaginal secretions is extremely valuable in diagnosis, with a sensitivity of 93% and specificity of 70%.

Although cultures for *G. vaginalis* are positive in almost all cases of BV, *G. vaginalis* may be detected in 50%–60% of women who do not meet the diagnostic criteria for BV. Accordingly, vaginal culture has no part in the diagnosis of BV. DNA probes for G. vaginalis are both sensitive (95%) and specific (99%), but are not widely used by practitioners because of costs and lack of insurance reimbursement. Diagnostic tests are now available for rapid diagnosis measuring pH, amines, or sialidase.

Management

The most widely used oral therapy remains to be metronidazole or tinidazole [28]. Most studies using multiple divided dose metronidazole regimens of 800–1200 mg/day for 1 week achieved clinical cure rates in excess of 90% immediately, and of approximately 80% at 4 weeks. Although single-dose therapy with 2 g metronidazole achieves comparable immediate clinical response rates, higher recurrence rates have been reported. CDC-recommended regimen is metronidazole 500 mg twice daily for 7 days [28]. The beneficial effect of metronidazole results predominantly from its antianaerobic activity and because *G. vaginalis* is susceptible to the hydroxymetabolites of metronidazole. Although *Mycoplasma hominis* and *Mobiluncus curtisii* are resistant to metronidazole, the organisms are usually not detected at follow-up visits of successfully treated patients. Similarly, metronidazole and tinidazole are considered therapeutical equivalent, although tinidazole has fewer of the commonly experienced side effects.

Topical therapy with 2% clindamycin cream once daily for 7 days, clindamycin ovules for 3 days, or metronidazole gel 0.75% administered daily for 5 days have been shown to be as effective as oral metronidazole, without any of the side effects of the latter.

In the past, asymptomatic BV was not treated, especially because patients often improve spontaneously over several months. However, the growing evidence linking asymptomatic BV with numerous obstetric and gynecological upper tract complications has caused reassessment of this policy, especially with additional convenient topical therapies. Asymptomatic BV should be treated before pregnancy, in women with cervical abnormalities and before elective gynecological surgery. Routine screening for and treatment of asymptomatic BV in pregnancy remains controversial, pending the outcome of studies proving that therapy of BV reduces preterm delivery and prematurity [28,29].

Despite indirect evidence of sexual transmission, no study has documented reduced recurrent rates of BV in women whose partners have been treated with a variety of regimens, including metronidazole. Accordingly, most clinicians do not routinely treat male partners.

After therapy with oral metronidazole, approximately 30% of patients initially responding experience recurrence of symptoms within 3 months. Reasons for recurrence are unclear, including the possibility of reinfection, but recurrence more likely reflects vaginal relapse, with failure to eradicate the offending organisms and reestablish the normal protective *Lactobacillus* sp.–dominant vaginal flora. Management of BV relapse includes oral or vaginal metronidazole, or topical clindamycin, usually prescribed for 14 days. New experimental approaches including exogenous *Lactobacillus* sp. recolonization using selected bacteria-containing suppositories have been encouraging. Maintenance antimicrobial agents administered twice weekly for 4–6 months have been reasonably effective but results less than desirable [30].

TRICHOMONIASIS

Epidemiology

Studies estimate that 3–5 million American women contract trichomoniasis annually, with a worldwide distribution of approximately 180 million annual cases [31]. The prevalence of trichomoniasis correlates with the overall level of sexual activity of the specific group of women under study, being diagnosed in about 5% of women in family planning clinics, in 13%–25% of women attending gynecology clinics, in 50%–75% of prostitutes, and in 7%–35% of women in STD clinics [31]. In many industrialized countries, recent surveys indicate a decline in the incidence of trichomoniasis.

Pathogenesis and Pathology

Sexual transmission is the dominant method of introduction of *Trichomonas vaginalis* into the vagina. *T. vaginalis* was identified in the urethra of 70% of men who had had sexual contact with infected women within the previous 48 hours. There is also a high prevalence of gonorrhea in women with trichomoniasis, and both of these are significantly associated with the use of nonbarrier methods of contraception.

Recurrent trichomoniasis is common and is indicative of lack of significant protective immunity. Nevertheless, an immune response to *Trichomonas* spp. does develop, as indicated by low titers of serum antibody, but this is insufficient for diagnostic serology. Antitrichomonal IgA has been detected in vaginal secretions, but a protective role is not defined. The predominant host defense response is provided by the numerous PMNs, which respond to chemotactic substances released by trichomonads and are capable of killing *T. vaginalis* without ingesting trichomonads. *T. vaginalis* destroys epithelial cells by direct cell contact and cytotoxicity. The urethral, paraurethral, Bartholin's, and Skeene's glands are infected in the majority of patients, and organisms are occasionally isolated from bladder urine.

Prevention

Sexual transmission of trichomonads is efficiently prevented by use of barrier contraception. Spermicidal agents such as nonoxynol-9 also reduce transmission. Reinfection of women is common, hence the mandatory requirement of treatment, preferably simultaneously, of all sexual partners with metronidazole. Women can acquire the disease from other women, but men do not usually transmit infection to other men.

Clinical Features

Infection with *Trichomonas* spp. in women ranges from an asymptomatic carrier state to severe acute inflammatory disease [32]. Vaginal discharge is reported by 50%–75% of women diagnosed with trichomoniasis; however, the discharge is not always described as malodorous. Pruritus occurs in 25%–50% of patients and is often severe. Other infrequent symptoms include dyspareunia, dysuria, and, rarely, frequency of micturition. Lower abdominal pain occurs in fewer than 10% of patients and should alert the physician to the possibility of concomitant salpingitis caused by other organisms. Symptoms of acute trichomoniasis often appear during or immediately after menstruation. Although controversial, the incubation period has been estimated to range from 3 to 28 days [32].

Physical findings represent a spectrum depending on the severity of disease. Vulvar findings may be absent but are typically characterized in severe cases by diffuse vulvar erythema (10%–33%), edema, and a copious, profuse, and malodorous vaginal discharge, which is often described as being yellow-green and frothy, but is frequently grayish-white [32]. Frothiness is seen in a minority of patients and is more commonly seen in BV.

The vaginal walls are erythematous and in severe cases may be granular in appearance. Punctate hemorrhages (colpitis macularis) of the cervix may result in a strawberry-like appearance that, although apparent to the naked eye in only 1%–2% of patients, is present in 45% of cases on colposcopy.

The clinical course of trichomoniasis in pregnancy is identical to that seen in the nonpregnant state, and when untreated, it is associated with premature rupture of membranes and prematurity. Trichomoniasis is reported to facilitate HIV transmission. Trichomoniasis is a risk factor for the development of posthysterectomy cellulitis, tubal infertility, cervical neoplasma, and pelvic inflammatory disease [33].

Diagnosis

None of the clinical features of vaginitis caused by *Trichomonas* spp. are sufficiently specific to allow a diagnosis of trichomonal infection based on signs and symptoms alone. Definitive diagnosis requires the demonstration of the organism. Vaginal pH is markedly elevated, almost always above 5.0, and not infrequently 6.0. On saline microscopy, an increase in the number of PMNs is almost invariably present. The ovoid parasites are slightly larger than PMNs and are best recognized by their motility. The wet mount is positive in only 40%–80% of cases (low sensitivity). Gram stain is of little value because of its inability to differentiate PMNs from nonmotile trichomonads, and the use of Giemsa, acridine orange, and other stains has no advantage over saline preparations. Although trichomonads are often seen on Papanicolaou smears, this method has a sensitivity of only 60%–70% when compared with saline preparation microscopy, and false-positive results are not infrequently reported.

Several equivalent culture medium methods are available, and growth is usually detected within 48 hours. Culture, including “InPouch,” has now been replaced by PCR molecular detection of trichomonas DNA and should be considered in patients with vaginitis in whom an elevated pH is found together with PMN excess and absence of motile trichomonads [34].

Management

Therapy is indicated in all nonpregnant women diagnosed with trichomonas vaginitis even if asymptomatic and consists of administering the 5-nitroimidazole group of drugs—metronidazole, tinidazole, spcnidazole, and ornidazole—which are all of similar efficacy [9]. Oral therapy as opposed to topical vaginal therapy is preferred because of the frequency of infection of the urethra and periurethral glands, which provide sources for endogenous recurrence [28]. Treatment of all sexual partners is mandatory.

Treatment consists of oral metronidazole, 500 mg q12h for 7 days, which has a cure rate of 95%. Comparable results have been obtained with a single oral dose of 2 g metronidazole, achieving cure rates of 82%–88%. The latter cure rate increases to greater than 90% when sexual partners are treated simultaneously. The advantages of single-dose therapy include better patient compliance, lower total dose, shorter period of alcohol avoidance, and possibly decreased incidence of subsequent vaginitis caused by *Candida* spp. A disadvantage of single-dose therapy is the need to insist on simultaneous treatment of sexual partners.

The 5-nitroimidazoles are not in themselves trichomonacidal, but low-redox proteins reduce the nitro group, resulting in the formation of highly cytotoxic products within the organisms. Aerobic conditions interfere with this reduction process and decrease the antianaerobic activity of the 5-nitroimdazoles. Most strains of *T. vaginalis* are highly susceptible to metronidazole, with minimum inhibitory concentrations of 1 mg/L. Similar efficacy results are reported with tinidazole but the latter has a superior tolerance profile.

Patients not responding to an initial course often respond to an additional standard course of 7-day therapy. Some patients are refractory to repeated courses of therapy even when compliance is assured and sexual partners are known to have been treated. If reinfection is excluded, these rare patients may have strains of *T. vaginalis* that are resistant to metronidazole, which can be confirmed in vitro. Increased doses of metronidazole and longer duration of therapy are necessary to cure these refractory patients. The patients should be given maximal tolerated dosages of oral metronidazole of 2–4 g/day for 10–14 days. Rarely, intravenous metronidazole, in dosages as high as 2–4 g/day, may be necessary, with careful monitoring for drug toxicity. Considerable success has been observed in treating resistant infections with oral tinidazole [35]. Most investigators use high-dose tinidazole 1–4 g/day for 14 days [35]. Rare patients not responding to nitroimidazoles can be treated with topical paramomycin.

Side effects of metronidazole include an unpleasant or metallic taste. Other common side effects include nausea (10%), transient neutropenia (7.5%), and a disulfiram-like effect when alcohol is ingested. Caution should be taken when 5-nitroimidazoles are used in patients taking warfarin. Long-term and high-dose therapy increase the risk of neutropenia and peripheral neuropathy.

Treatment of symptomatic trichomoniasis in pregnancy is identical [28]. Metronidazole readily crosses the placenta and because of concern for teratogenicity, some consider it prudent to avoid its use in the first trimester of pregnancy. More recently investigators have become reassured with the use of metronidazole throughout pregnancy.

ATROPHIC VAGINITIS

Atrophic vaginitis, also called urogenital atrophy, refers to the extremely common condition that is characterized by atrophy of the vagina, vestibule, and vulva as a consequence of estrogen deficiency [1,36]. The dominant target of estrogen deficiency is the vaginal epithelium, which loses its rugosity and undergoes progressive thinning and atrophy. Simultaneously but often less conspicuous is progressive thinning of the vestibular epithelium. Atrophy of the vaginal epithelial lining is accompanied by reduced glycogen synthesis, which serves as a critical substrate for resident bacteria that break down glycogen to produce organic acid most importantly lactic acid further resulting in the loss of *Lactobacillus* species, the dominant component of vaginal microbiota. Accordingly, a consistent consequence of estrogen deficiency is elevation of vaginal pH, usually above 5.0. Low estrogen levels reduce vaginal secretions that result in vaginal dryness but not infrequently and paradoxically a vaginal discharge is perceived to exist, or may in fact present as a watery discharge. Atrophic vaginitis typically occurs in menopausal women, but it can also occur in women at any age who have a decrease in estrogenic stimulation to this area of the genitalia. In premenopausal women, hypoestrogenic settings include postpartum, lactation, and during administration of antiestrogenic drugs. Vaginal atrophy that follows the gradual decline of estrogen production is often associated with manifestations and at other sites including the bladder floor and urethra. Accordingly, urethral and bladder symptoms may be a manifestation of estrogen deficiency including dysuria. The loss of estrogen also has an effect on the bladder lining facilitating the development of bacterial cystitis in aging women. Another impact of estrogen deficiency relates to the loss of muscle tone and dilatation of the vaginal introitus, as well as contributing to the development of prolapse of bladder, uterus, and rectum.

Clinical Manifestations

The earliest effects of estrogen deficiency are progressive atrophy and diminished vaginal secretions manifesting as vaginal dryness experienced during intercourse. While early symptoms may be relieved in part by the use of vaginal lubricants, invariably, progressive estrogen deficiency will not be compensated for by the use of such lubricants. Ultimately, adequate vaginal lubrication for pain-free intercourse will require adequate estrogenic effect on the vaginal epithelium. Vaginal dryness is often experienced by women long before the onset of amenorrhea or the development of systemic vasomotor symptoms and is followed by dyspareunia. Dyspareunia is initially superficial or entry in nature, but with progression of the vaginal atrophy, the discomfort and pain will be experienced throughout and following intercourse with discomfort and irritation and even itching, lasting for several days after intercourse. With advanced atrophy, patients may complain of postcoital bleeding as a result of the susceptibility of the thinned vaginal epithelium to the effects of local friction and trauma.

Diagnosis

Vaginal atrophy and estrogen deficiency can be easily diagnosed without the use of sophisticated testing. The vaginal pH becomes elevated in excess of 4.5 and may reach levels in excess of 6. The vaginal pH is an excellent marker of estrogen deficiency. The elevated pH is a consequence of the loss of the lactic and other organic acid producing bacteria. Lactic acid–producing bacteria are replaced in part by gram-negative organisms, usually coliform, which in their own right are not pathogenic. On wet mount microscopy, the paucity of the typical rod-shaped bacterial morphotypes is apparent. Another important diagnostic feature is the appearance of parabasal epithelial cells reflecting a lack of maturation of basal and parabasal cells in the absence of adequate estrogen stimulation to achieve full maturation effect. Increase in the number of parabasal cells will confirm the diagnosis in the presence of elevated pH and altered bacterial flora. It is also unnecessary and often misleading to measure serum estradiol levels. The latter test is redundant and does not parallel vaginal findings. Neither does receipt of oral nor transcutaneous estrogen products preclude the development of vaginal atrophy.

Treatment

One of the most remarkable biological miracles is the reversible nature of vaginal atrophy. Following adequate estrogen replacement, especially by the vaginal route, a rapid transformation can be anticipated with reversal of the vaginal thinning together with reconstitution of healthy, protective bacterial flora with a dominant lactobacillus morphotype as well as the return to normal vaginal pH and accompanied by the disappearance of parabasal cells [37]. This dramatic change can be expected within 4–6 weeks of adequate estrogen replacement therapy. A number of local vaginal treatments may be used to rectify atrophic vaginitis. These include intravaginal estradiol as creams or vaginal suppositories of estradiol. Alternatively, intravaginal estriol may be used. Not infrequently, vaginal atrophy continues and progresses in the presence of systemic estrogen therapy. Accordingly, one should always insist on local intravaginal therapy. A more recent alternative is the use of the estrogen releasing vaginal rings of which several varieties are available. One can anticipate a return to vaginal health within 1–2 months although the use of lubricants during intercourse may still be required.

NONINFECTIOUS VAGINITIS AND VULVITIS

Women often present with acute or chronic vulvovaginal symptoms of noninfectious etiology. These symptoms are indistinguishable from those of infectious syndromes but are most commonly confused with those of acute *Candida* vaginitis (e.g., pruritus, irritation, burning, soreness, variable discharge). Noninfectious causes of vaginitis and vulvitis include physical irritants (e.g., minipads), chemical irritants (e.g., spermicides, Betadine, topical antimycotics, soaps and perfumes, topical 5-flurouracil), and allergens responsible for immunological acute and chronic hypersensitivity reactions, including contact dermatitis (e.g., latex condoms, antimycotic creams). There is an enormous list of topical factors that are responsible for local inflammatory reactions and symptoms, and many more have yet to be defined. Depending on the site of contact, symptoms may be vaginal or vulvar. A noninfectious mechanism may coexist with or follow an infectious process and should be considered when (1) the three common infectious causes of vulvovaginal symptoms, as well as hormone deficiency, are excluded, (2) the vaginal pH and saline content are normal, and (3) KOH microscopy and a yeast culture are negative. Unfortunately, given the anticipated 20% colonization rates in normal asymptomatic women, a positive yeast culture sometimes reflects the presence of an “innocent bystander" organism rather than the cause of a patient's vulvovaginal symptoms. The only logical way of establishing the role of *Candida* in this context is to treat the patient with an oral antifungal agent and assess the clinical response.

Once a local chemical, irritant, or allergic reaction is suspected as the cause of vaginitis and/or vulvitis, a detailed inquiry into possible causal factors is essential. Offending agents or behaviors should be eliminated whenever possible, including the avoidance of chemical irritants and allergens (e.g., soaps, detergents). The immediate management of severe vulvovaginal symptoms of noninfectious etiology should not rely on topical corticosteroids, which are rarely the solution to such symptoms; moreover, high-potency steroid creams often cause intense burning. Local relief measures include sodium bicarbonate sitz baths and oral antihistamines.

58 Pregnancy and Childbirth and the Effect on the Pelvic Floor

Philip Toozs-Hobson, Aneta Obloza, and Sara Webb

INTRODUCTION

Over the past few decades, there has been an increasing recognition of the consequences of childbirth on the physical and psychological well-being of a woman. In 1991, MacArthur et al. [1] undertook a postal survey of 11,701 women between 13 months to 9 years after delivery and found that 47% experienced at least one or more health problems within 3 months of delivery. Symptoms persisting for a minimum of 6 weeks included backache, headache, hemorrhoids, depression, and bowel and bladder symptoms. Glazener et al. [2] undertook a similar postnatal symptom on three occasions after childbirth; 85% of women experienced one new symptom during the first 8 weeks and 76% reported one or more health problems persisting for up to 18 months. Sleep and Grant [3] reported that 15% of women experience dyspareunia up to 3 years after a normal vaginal delivery and up to 8% experience perineal pain 12 weeks after a normal vaginal delivery. Interesting perineal pain can occur even without perineal trauma and women who sustain anal sphincter damage have significantly greater pain ratings at 7 weeks after delivery compared to those with lesser degrees of perineal trauma [4]. However, although health problems seem to be common after childbirth, it appears women often do not seek medical attention [1]. This chapter will concentrate on urinary and fecal incontinence, which have a significant negative impact on quality of life and sexual function particularly if both are present [5].

Urinary and/or fecal incontinence and genital prolapse are often considered to be inevitable sequelae of a vaginal birth. One in every three women will experience some symptoms of incontinence during her lifetime and, of these, up to 65% will recall that it began either during pregnancy or after childbirth [5]. Certainly in prospective series, antenatal leakage was a strong risk factor for postnatal leakage [6]. Despite this, much of the clinical and epidemiological studies strongly indicate that women who undergo a vaginal delivery are at higher risk of subsequent incontinence than nulliparous women and those who undergo cesarean section (CS). This is most likely related to the detrimental impact of vaginal delivery on the pelvic floor [7–10]. Furthermore, it appears that the first vaginal delivery is the time when women sustain the most significant damage [8,11]. However, the effects of mode of delivery in higher-order pregnancies are less certain.

Supporting these findings are several studies showing a relationship between vaginal delivery and mechanical and neurological damage to the pelvic floor, which are related to the development of urinary or anal incontinence or both [11–13]. More recently, interest has turned to looking the more subtle changes with sensory nerve function [14] and further work in this area will undoubtedly add to our knowledge in the future. Other factors of relevance include an increased predisposition to pelvic floor trauma and, thus, incontinence and prolapse, due to an inherent weakness of collagen within the pelvic floor fascia [15,16].

This chapter focuses on the effect of pregnancy and childbirth on the pelvic floor and discusses the possible mechanisms by which pelvic floor damage may occur and its long-term sequelae.

MECHANISMS OF INJURY TO THE PELVIC FLOOR

There are several mechanisms of pelvic floor injury: direct muscle trauma, nerve injury, and connective tissue damage disrupting the urethral and anal sphincters and their support (Figure 58.1).

Direct Perineal Trauma

Direct perineal trauma from perineal laceration and episiotomy is a well-known complication of vaginal delivery. Episiotomy [17] is one of the commonest surgical interventions and was traditionally advocated to decrease perineal damage; it reduces anterior perineal laceration but has not been shown to reduce pelvic floor damage, urinary, or fecal incontinence or protect the newborn from intracranial trauma.

The long-term sequelae of perineal injuries include pain, dyspareunia, fistulae, and anal incontinence [11,17,18]. The incidence of lacerations involving the anal sphincter has been reported as 0%–6.4% when an episiotomy has not been performed, 0.2%–23.9% after a midline episiotomy, and 0%–9% after a mediolateral episiotomy [17]. There does not, however, seem to be a significant association between episiotomy and the development of urinary incontinence [19].

Severity and frequency of postpartum dyspareunia has been related to perineal trauma and obstetric instrumentation, with a quicker resumption of sexual activity in those with an intact perineum versus those women who have a spontaneous laceration or trauma [19,20]. Despite all these features, pelvic floor strength, as a separate entity to dispensability, may also be an important factor for predicting vaginal birth [21]; however, higher vaginal resting pressure (VRP) at midpregnancy was associated with a prolonged second stage of labor. There was no influence of VRP, PFM strength, or endurance on the rate of acute CS, prolonged second stage, instrumental vaginal delivery, episiotomy, and third- and fourth-degree perineal tear [22].

Muscle Trauma

Traditionally, much has been made of the obstetric factors [23] associated with childbirth. The physical characteristics of the soft tissue in the female pelvis, however, play an important role in successful vaginal delivery. Women with larger levator hiatus dimensions at rest and during contraction at 37 weeks gestation had a shorter duration of the active second stage. Those who had normal vaginal deliveries had significantly larger transverse diameter and levator hiatus area at rest, during contraction, and during Valsalva maneuver compared with women who had instrumental deliveries [24]. Measurement of distensibility [25] of the female pelvic floor was also shown to potentially influence mode of delivery and, in the long term, contribute to pelvic organ dysfunction [26].

An increase of all hiatal dimensions as well as bladder neck mobility was found from 21 weeks to 37 weeks gestation in nulliparous pregnant women [27]. Changes to the pelvic floor may occur from distension during descent of the fetal head and maternal expulsive efforts during the active second stage of labor. Peschers et al. [28] evaluated pelvic floor strength by means of palpation, perineometry, and perineal ultrasound and found that pelvic floor muscle strength was significantly decreased after vaginal delivery compared to CS at 3–8 days postpartum. However, at 6–10 weeks postpartum, there was no significant difference from antenatal values except for a lower intravaginal pressure in nulliparous women. Therefore, although pelvic strength is impaired shortly after vaginal birth, it recovers in most women within 2 months after the first pregnancy. This finding was also found when looking at the levator hiatus with ultrasound [29,30] where recovery seemed to occur through a reduction in the hiatus (possible recovery of flaccid denervation) and in the levator muscle's ability to contract on squeeze.

This recovery, however, is affected by avulsion injuries, which may delay or prevent recovery [31].

In the longer term, that is, 2 years, the levator ani muscle still showed a significantly larger hiatal area after vaginal delivery compared to CS [32]. Two retrospective studies [33,34] have highlighted the relationship between increased levator hiatus and prolapse, but these have not shown cause and effect. Further evidence of childbirth influencing subsequent pelvic floor dysfunction was examined in a 12-year follow-up after the childbirth using a patient-reported measure (pelvic organ prolapse symptom score [POP-SS]) in relation to objective measurement of the pelvic organ prolapsed—the pelvic organ prolapse quantification (POP-Q) system. Women who had had at least one forceps delivery had significantly higher (worse) prolapse symptom scores, POP-SS 2.91 ($p < 0.007$). The association between women's prolapse symptoms and mode of delivery (more symptoms after at least one forceps delivery) suggests that forceps delivery has an adverse effect on pelvic floor function, while delivery exclusively by CS is not protective [35].

Prospective studies, evaluating pelvic floor strength at 1 year postpartum using perineometry, found no difference between degree of perineal trauma and subsequent muscle strength [36]. However, another large study of 519 women evaluated at 3 months postpartum using symptom analysis and vaginal perineometry found that the women who had sustained an episiotomy had lower pelvic floor strength and more perineal pain and dyspareunia than those with intact perineums of first- and second-degree lacerations. There was no difference in symptoms of urinary and anal incontinence [37].

Two studies have simulated delivery using biomechanical modeling of the pelvic floor muscles during the passage of the fetal head through the birth canal [38,39] and demonstrated strain ratios varying from 1.6 to 2.73 for different parts of the levator ani muscle. They also showed that the pubococcygeus–perineal body complex undergoes a maximum of 3.26 stretches to accommodate crowning fetal head with the tissue stretch ratios proportional to both the fetal head flexion and size.

In the magnetic resonance imaging (MRI)-simulated model of vaginal birth [40], a maximum stretch ratio of 3.5 was seen in the posteromedial aspect of the puborectalis muscle. Simulated decrease in stiffness of the lateral attachments of the levator ani (iliococcygeus to tendinous arch levator ani attachments) resulted in decrease of the maximal levator stretch. Authors hypothesized that a more rigid levator in nulliparous women may be subjected to higher stretch during childbirth than multiparous. Thus, the first vaginal delivery may predominantly contribute to urinary incontinence development, which is associated with bladder neck mobility.

Subsequent research has examined the sheer forces applied to the pelvic floor. Ashton-Miller et al. [41] assessed the biomechanics of the pelvic floor muscles, demonstrating the pelvic floor sustains a pressure of 37N while standing and 19N in supine position. Straining to pass a stool increases the pressure to 92N. However, these pressures rise dramatically during an active second stage of labor to 120N during each contraction with active pushing of 113N with instrumental delivery via vacuum suction, and for forceps, it reaches 200N. A further study demonstrated that contracting pelvic floor muscles become stiffer and may be an obstacle to descending fetal head and suggested that pelvic floor muscles exercises may improve muscle control and flexibility [42]. This may result in higher risk of muscle stretch injury near the levator hiatus with a tearing direction perpendicular to the hiatal edge. Predicted hiatal stretch reached the ratio of 3.55 [43].

Women who delivered vaginally showed a persistent significant increase in hiatal dimensions on Valsalva, while women who delivered by prelabor or first stage CS showed no significant changes in hiatal dimensions on Valsalva [44]. What is interesting is that women who deliver vaginally or by elective CS have different antenatal pelvic floor characteristics [6], demonstrating that there may also be tissue factors that may predispose what type of delivery women will have. This has been investigated in animal models [45] whereby analysis of the biochemical tissue composition and biochemical properties of the ovine vagina showed that pregnancy influences remodeling tissue by increasing level of elastin, decreasing collagen, and increasing smooth muscle layer, thus allowing vaginal extensibility but at the cost of greater tissue weakness and less likelihood to return to original dimensions after a repetitive stress. In one of the few human studies, Lavin et al. [46] also demonstrated significant changes in the characteristics of the rectus sheath in pregnancy when compared with nonpregnant women. Postdelivery animal model demonstrated that the vagina undergoes various molecular remodeling that includes both synthesis and proteolytic degradation of extracellular matrix (ECM) proteins [47]. This process may have a genetic component through the homeobox genes (HOX). HOXA11 gene is responsible for the regulation of morphology and integrity of the uterosacral ligaments and expression of ECM proteins during cellular cycle. This finding may explain both the adaptive mechanism soft tissue undergoes to allow vaginal birth and also the development of pelvic organ prolapse [48].

Nerve Damage

The pudendal nerve is particularly susceptible to compression and damage at the point where it curves round the ischial spine and enters the pudendal canal enclosed in a tight fibrous sheath. Nerve damage has been shown to occur in patients with a history of chronic straining on defecation who show increased pudendal nerve terminal motor latencies [49]. Childbirth-induced denervation injuries of the pubococcygeus and external sphincter muscles may occur by a similar mechanism and have been reported after 42%–80% of vaginal deliveries [12,13]. Pudendal terminal latency testing itself is a poor discriminator of nerve function as it is a coarse test that requires a significant injury (greater than 75%) to demonstrate impairment. A better test as previously mentioned is the EMG, but this requires more invasive testing, and so is less acceptable [13].

LOWER URINARY TRACT IN PREGNANCY AND AFTER DELIVERY

Lower urinary tract symptoms are very common in pregnancy. Several large epidemiological studies have assessed the prevalence of urinary symptoms in pregnancy, mostly focusing on the symptom of stress incontinence. Most of these symptoms may be a consequence of the normal anatomic and physiological changes that occur in pregnancy; however, superimposed on these changes may be further pathological changes as a consequence of tissue damage, from either pregnancy or labor, resulting in persistent symptoms. The distinction between normal physiological changes and transient or permanent pathophysiology is often not clear and may be a continuum.

Anatomic and Physiological Changes

The urinary tract undergoes both structural and functional changes during pregnancy and after delivery. These changes may be specific in response to pregnancy and, in some women, may be compounded by pathological changes that persist after delivery.

In normal pregnancy, the kidneys increase by 1 cm in length due to an increase in vascular volume and interstitial space. Dilation of the ureters is a well-known phenomenon in pregnancy and hydroureter is noted in approximately 90% of pregnant women by the third trimester. This dilation is more marked on the right compared to the left side, probably related to the relative dextrorotation of the uterus. There is a 40%–50% increase in glomerular filtration rate and a 60%–80% increase in the effective renal plasma flow [50]. As a result, plasma creatinine, urea, and urate values are lower than the normal range for nonpregnant women.

The bladder is passively drawn upward and anteriorly as the uterus enlarges, resulting in lengthening of the urethra [51]. The urethral mucosa becomes more hyperemic and congested in pregnancy in response to the increase in circulating estrogen levels. The detrusor muscle also hypertrophies in response to estrogen. After delivery, cystoscopy of the bladder shows changes such as mucosal congestion, submucosal hemorrhage, and capillary oozing, especially around the bladder neck, trigone, and ureteric orifices. These changes have been seen in association with a decrease in bladder sensation and tone [52] and are most marked in those who underwent vaginal delivery [53].

Studies assessing bladder capacity have revealed conflicting results, with most early studies using simple cystometry only. Muellner [54] reported an increase in bladder capacity to an average of 1300 mL in the third trimester due to bladder hypotonia, with a return to normal values postpartum. However, other investigators found no change in bladder capacity in the first trimester and a reduced bladder capacity in the third trimester in association with increased detrusor irritability, rather than bladder hypotonia [55]. Dual-channel cystometry studies have found that all urodynamic variables, such as first sensation and maximum bladder capacity, are lower in pregnancy and postpartum compared to a nonpregnant population, and this may account for symptoms of frequency, nocturia, and urgency [56].

PREGNANCY AND URINARY SYMPTOMS

Frequency and Nocturia

These are among the commonest and earliest symptoms to develop in pregnancy. Normal nonpregnant women void between four and six times per day and rarely at night.

Using a definition of frequency as at least seven daytime voids and one nighttime void, Francis [55] studied the voiding habits in 400 healthy women during and after an uncomplicated pregnancy and compared them with 50 healthy nonpregnant patients of similar age. Frequency was reported by 59% in early pregnancy, 61% in midpregnancy, and 81% in late pregnancy. Parboosingh and Doig [57] defined nocturia as at least three nighttime voids and, following the questioning of 873 healthy antenatal patients, found that nearly 66% experienced nocturia by the third trimester. Cutner et al. [58] assessed lower urinary tract symptoms in 47 women undergoing termination of pregnancy at 6–15 weeks gestation and found that 40% complained of frequency and 23% of nocturia. The cause of frequency was not related to bladder capacity or the effect of posture, but due to the polydipsia and polyuria of pregnancy [57].

Both fluid intake and output rise rapidly in the first trimester, remaining constant until the third trimester, when a decrease in sodium excretion leads to a decrease in output. Despite this, frequency persists related to the pressure on the bladder by the uterus. Cutner et al. [58] found that there was a correlation between the maximum voided volumes and first sensation to void and maximum bladder capacity, which was, in turn, related to the presence of low compliance. There was no correlation between the maximum voided volumes and diurnal frequency and nocturia. Parboosingh and Doig also measured mean urine flow and solute excretion in 24 hour and overnight collections in 100 normal and nonpregnant women. An increase in sodium excretion was the major reason for increased nighttime voiding as well as the mobilization of dependent edema at night in the recumbent position.

Voiding Difficulties

Urinary hesitancy may be found in up to 27% of patients in the first two trimesters [59]. Fischer and Kittel [60] assessed flow rates in 290 women during pregnancy and found that there was a significant increase in peak flow rates in the second and third trimesters compared to controls and early pregnancy, but these higher flow rates were associated with larger voided volumes. Cutner et al. [58] assessed flow rates in pregnancy, adjusting for volume voided, and found no difference in women complaining of hesitancy or incomplete emptying, compared to pregnant women with normal voiding.

Urinary retention can occur in pregnancy associated with the enlargement of a retroverted uterus with subsequent entrapment of the fundus below the sacral promontory. Other causes include an enlarging fibroid or a pelvic mass. This retention usually resolves by 16 weeks gestation as the uterus grows out of the pelvis and can be managed in the interim with either bladder drainage or intermittent self-catheterization. Alternatively, manual reduction of the uterus can be performed or a Hodge pessary may be inserted to maintain uterine position and relieve the obstruction on the bladder neck.

Postpartum urinary retention is common, with a reported incidence of 1.7%–17.9% [61]. Risk factors include a first labor, instrumental delivery epidural analgesia, and a longer duration of labor (≥800 minutes) [62]. Studies have looked at sensation after delivery [63] and found that the bladder can take up to 8 hours to regain sensation after the last top-up of an epidural. Overdistension of the bladder may occur during this period, leading to permanent detrusor dysfunction.

Urinary Incontinence

Incontinence is a common symptom associated with pregnancy and has been reported in up to 85% of women [64]. The risk of urinary incontinence increases with advancing gestation. Francis [63] found that in the first trimester of pregnancy 16% of women complained of stress incontinence and 34% in the second half of pregnancy. Stanton et al. [65] assessed the prevalence of both stress and urge incontinence at 32 weeks gestation and found an incidence of 36% and 13%, respectively.

Viktrup and Lose [8] interviewed 305 primiparae and found that 39% had stress incontinence before, during, or after pregnancy and 7% developed de novo stress incontinence after delivery. The association with these obstetric risk factors was lost by 3 months postpartum. Only 3% had incontinence at 1 year. However, in a subsequent follow-up study of the original cohort of 278 women, they reported a prevalence of stress incontinence of 30% at 5 years. In those without symptoms after the first delivery, the incidence was 19%; however, in those who reported stress incontinence 3 months after the first delivery, there was a 92% risk of having stress incontinence 5 years later [8]. A prospective cohort study of 949 women undertaken to find risk factors for postpartum stress incontinence at 3 months found that urinary incontinence was experienced by 22.3% before pregnancy, 65.1% during the third trimester, and 31.1% after delivery [19]. New onset urinary incontinence was more common in parous compared to nulliparous women. Postpartum urinary incontinence was independently associated with incontinence prior to pregnancy and beginning during pregnancy, even among those having a CS. This study highlights the high proportion of women who suffer from urinary incontinence as 15.4% of nulliparae had prepregnancy incontinence. It confirms previous data that have found that the presence of antenatal and prepregnancy stress incontinence seems to increase the risk of future stress incontinence [66,67].

The pattern of the development of incontinence during pregnancy, with rapid postpartum recovery followed by a steady decline of continence over time, suggests a dual mechanism of nerve and tissue damage. The evidence regarding the contribution of obstetric factors to the development of stress incontinence is conflicting. The data are unclear whether it is pregnancy or the birth itself that is the major contributor to postpartum incontinence. Some investigators have found a relationship with the duration of the second stage of labor [68,69] and birth weight [1]. Conversely, other investigators have found no significant correlation between stress incontinence and fetal head circumference [70], second stage of labor [1,71], or birth weight [90–92]. However, most of these studies are relatively small population studies that differ widely in their questioning techniques and definition of stress incontinence. The largest community-based epidemiological study of incontinence (EPINCONT study) [13] assessed 15,307 women who were younger than 65 years and were grouped according to obstetric performance as “had not delivered,” “delivered only by CS,” or “only vaginal deliveries.” The authors reported that in the nulliparous group, the prevalence of any incontinence was 10.1%, 15.9% in the CS only group, and 21.0% in the vaginal delivery only group. Thus, pregnancy itself rather than the mode of delivery may also be an etiological factor in the development of urinary incontinence.

The effect of epidural analgesia is unclear. Epidural analgesia has been reported to be more protective than pudendal block against postpartum stress incontinence [90]. However, this has not been supported by other research that has found a higher incidence of stress incontinence in those who received epidural analgesia than those who did not [92]. Jackson et al. [89] found that the incidence of stress incontinence increased in women delivered with epidural analgesia, especially if the second stage of labor was longer than 120 minutes.

Changes in the Lower Urinary Tract and Pelvic Floor Related to the Development of Incontinence

The exact etiological mechanism of stress incontinence is unclear and probably multifactorial, related to nerve damage and/or physiological and structural changes of the lower urinary tract.

Functional Changes

Iosif and Ulmsten [72] compared urethral pressure profile measurements in pregnant women with stress incontinence with continent healthy women from an earlier study. They found that the absolute urethral length increased by an average of 6.7 mm and the functional urethral length by 4.8 mm. The maximum urethral closure pressure increased to 93 cmH_2O at 38 weeks and then dropped to prepregnancy values of 69 cmH_2O postpartum. These changes were not seen in women complaining of incontinence and are postulated to be a mechanism whereby continence is maintained despite an increase in intravesical pressure in pregnancy. This corresponds with other studies that have shown evidence of low urethral pressure in nonpregnant women with stress incontinence [59,73]. This increase in urethral closure pressure may be the result of an increase in urethral sphincter volume from increased blood flow. There is also an increase in the amplitude of vascular pulsations recorded from the urethral wall, especially in the first 16 weeks of pregnancy, which may be related to an increase in blood volume in pregnancy. Pregnant women with urodynamic stress incontinence showed a decrease in the amplitude of vascular pulsations in the periurethral plexus compared to continent women, suggesting that this affects urethral closure pressure [74]. Three-dimensional imaging of the urethral sphincter after vaginal delivery shows a reduction in sphincter volume, which has been implicated in the development of stress incontinence [75].

Cystometry in pregnancy has been performed by several workers. Chaliha et al. [63] found a high prevalence of urodynamic stress incontinence and detrusor overactivity. This was 8.7% and 8.1%, respectively, in the antenatal period and 5.0% and 6.8%, respectively, postpartum. The mean values for urodynamic variables in the third trimester and postpartum were lower than the values defined in a nonpregnant population and not related to obstetric or neonatal variables (Table 58.1). However, despite the high prevalence of symptoms in this study, there was poor correlation between symptoms and urodynamic findings, which agrees with data in nonpregnant women [76]. Therefore, these observed changes in bladder function were consistent with a pressure effect of a gravid uterus and not related to mode of delivery or neonatal factors.

Nerve Damage

Patients with urodynamic stress incontinence have been shown to have abnormal conduction in the perineal branch of the pudendal nerve, which innervates the periurethral striated muscle and pubococcygeus muscle [77,78]. This damage is likely to lead to a loss of striated muscle of the urethral sphincter [79]. The degree of pudendal nerve damage was greater in multiparous women and correlated with the use of forceps and a longer second stage of labor [77,78]. In 60% of these women, pudendal nerve latency had returned to normal at 2 months postpartum [12]. Using concentric needle electromyography and pudendal nerve conduction tests, Allen et al. [13] found evidence of denervation injury in 80% of women after delivery. Those women with a long (active) second stage of labor (>56.7 minutes) and a large baby (>3.41 kg) showed a greater degree of nerve damage.

Electromyography of the right and left pubococcygeus muscle has shown that childbirth induces both qualitative and quantitative changes, demonstrating sphincter weakness can be attributed to not only the loss of motor units but also the asynchronous activity in those units that remain [80].

Table 58.1 Urodynamic Values (Sitting and Standing Cystometry) and Urodynamic Diagnoses before and after Delivery

Urodynamic variable	**Antenatal values[a]**	**Postnatal values[a]**
Sit FDV (mL)	111 (70)	148 (83)
Sit SDV (mL)	188 (91)	217 (94)
Sit MXCC (mL)	301 (146)	299 (114)
Stand FDV (mL)	96 (69)	139 (90)
Stand SDV (mL)	167 (102)	209 (105)
Stand MXCC (mL)	239 (136) (*n* = 125)	271 (123) (*n* = 118)
MVP (cmH_2O)	38 (22) (*n* = 153)	32 (17) (*n* = 157)
Peak flow rate (mL/second)	28 (16.3)	23 (14)
Urodynamic stress incontinence	14 (9%)	8 (5%)
Detrusor overactivity	13 (8%)	11 (7%)

Structural Changes

Ultrasound studies have shown changes in bladder neck position and the urethral sphincter in relation to delivery. Peschers et al. [81] evaluated bladder neck position and mobility using perineal ultrasound at 8 weeks postpartum. Bladder neck position was significantly lower and bladder neck mobility increased after vaginal delivery compared with women who had an elective CS and nulligravid controls. Meyer et al. [82] noted a significant increase in bladder neck mobility after vaginal delivery in primiparae; however, bladder neck position was only lowered after forceps delivery.

Alterations in the urethral sphincter closure mechanism have previously been described in association with stress incontinence. Toozs-Hobson et al. [29] investigated 156 primigravid women in the third trimester and at 6 weeks and 6 months postpartum using a combination of transvaginal and transperineal ultrasound to measure the levator hiatus and bladder neck mobility at rest, maximum strain, and maximum Valsalva. Urethral sphincter volume was calculated using a three-dimensional imaging probe. They found that vaginal delivery was related to an increased bladder neck mobility and larger levator hiatus, with both antenatal and postpartum mobility greater in women who delivered vaginally. The urethral sphincter was smaller postdelivery independent of mode of delivery. These results are interesting but their long-term consequences are unclear as the findings were not related to symptoms. The authors postulated that the larger sphincter volume in pregnancy was a function of the tissue and hormonal effects of pregnancy. In addition, the finding that women delivered by CS showed less pelvic floor distensibility may suggest that this may predispose them to this mode of delivery due to inherent differences in pelvic floor tissues. This supports previous observations that increased bladder neck mobility is associated with vaginal delivery.

It has been suggested that there may be a group of women at an inherent increased risk of developing incontinence due to abnormalities in collagen [83], as the collagenous component of the connective tissue contributes to structural support of the bladder neck. In pregnancy, the tensile properties of the connective tissue are reduced, with a reduction in total collagen content and increase in glycosaminoglycans [57]. Changes in collagen may result in greater mobility of the bladder neck resulting in stress incontinence. In a study of 116 primigravidae, perineal ultrasound was used to assess bladder neck mobility. Women with antenatal bladder neck mobility >5 mm on linear movement (equivalent to >10° rotation) were found to be at higher risk of developing postpartum stress incontinence. Approximately 50% of this group reported stress incontinence at 3 months postpartum [84].

ANAL SPHINCTER MORPHOLOGY DURING PREGNANCY AND AFTER DELIVERY

Sultan et al. [85] examined 20 women before and after an elective CS and found that pregnancy did not have any significant effect on anal sphincter morphology and function.

FECAL INCONTINENCE

Fecal incontinence is a distressing social handicap and vaginal delivery is a major etiological factor [12,86]. MacArthur et al. [1] investigated the prevalence of postnatal fecal symptoms in a postal questionnaire study of 906 women 10 months after delivery and reported that 36 women (4%) developed de novo fecal incontinence. Six of these women became incontinent after an emergency CS but none after an elective CS. This estimate for fecal incontinence is conservative, as it did not inquire about incontinence of flatus that is probably more common and has been reported to be as high as 29% at 9 months after delivery in one study of 349 primiparous women [87].

Fecal incontinence is especially common after anal sphincter rupture, with a reported prevalence of 16%–47% [88]. Tezschner et al. [70] assessed the long-term impact of obstetric anal sphincter rupture on the frequency of urinary and anal incontinence. At 2–4 years postpartum, 42% of the 94 women in their study had anal incontinence, 32% had urinary incontinence, and 18% had both urinary and anal incontinence. Despite the high number of women with incontinence, only a few had sought medical advice.

Changes in the Anal Canal and Pelvic Floor Related to Anal Incontinence

The etiology of postpartum anal incontinence is complex and both nerve and mechanical trauma have been implicated.

Nerve Damage

Denervation injury of the pelvic floor may occur from traction and straining during vaginal delivery, similar to the mechanism of nerve damage reported in patients with chronic constipation, which may result in anorectal incontinence [89]. In 80% of women with idiopathic anorectal incontinence, there is histological evidence of denervation of the striated pelvic floor muscle, particularly the puborectalis and external anal sphincter muscles [90]. Serial measurements of pudendal nerve terminal motor latencies in patients with idiopathic anorectal incontinence show progressive damage from recurrent stretch injury during straining at stool [91].

This mechanism of strain-induced damage may occur during vaginal delivery. Denervation injuries of the pubococcygeus and external sphincter muscles have been reported after 42%–80% of vaginal deliveries [12,13]. The presence of neuropathy has been found to be related to the length of the second stage of labor, size of the baby, and instrumental delivery [92]. Sultan et al. [93] investigated pudendal nerve function before and after delivery and found that pudendal nerve terminal motor latencies were significantly prolonged, especially on the left side, which the authors postulated could be due to the unequal traction from the fetal head on the two sides of the pelvic floor during descent down the birth canal. However, no relationship between abnormal neurophysiology and symptoms of anal incontinence was shown.

Sensory nerve function may also be affected by nerve damage. The anal canal has a greater variety of afferent nerve endings than the rectum. These allow the detection of differences in touch, temperature, and pain in the anal canal. The rectum has a configuration of nerve plexuses that serve as specialized sensory receptors for distension for perception of fullness, urgency to defecate, and pain [94,95].

It is believed that sensory information is critical to the preservation of continence, and in patients with fecal incontinence, there is a significant reduction in the ability to perceive electrical and other forms of stimulation [96]. In pregnancy, however, the role of anal sensation is unclear as deficits in anal canal sensation appear to be transient and unrelated to the development of incontinence [97].

Anal Sphincter Trauma

The incidence of anal sphincter damage varies between 0.5% and 2.5% in centers where mediolateral episiotomy is practiced and 7% in units performing midline episiotomies [18,98]. The use of anal endosonography has enabled accurate visualization of the sphincters, thus providing strong direct evidence of the much higher incidence of previously unrecognized occult anal sphincter trauma after delivery and its importance in the pathophysiology of anal incontinence [99] (Figures 58.2 through 58.4). This can be diagnosed immediately after delivery if suspected [100].

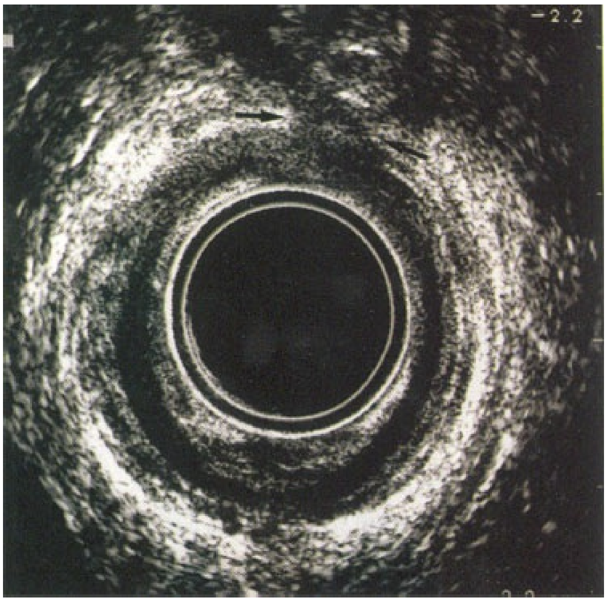

Figure 58.2 Two-dimensional image of the anal sphincter, demonstrating an external sphincter defect (arrows). The external sphincter appears hyperechoic surrounding the hypoechoic external sphincter. (From Chaliha, C., Pregnancy and childbirth and the effect on the pelvic floor, in: Cardozo, L. and Staskin, D., eds., *Textbook of Urogynaecology and Female Urology*, 3rd edn., Informa Healthcare, London, U.K., 2010, pp. 554–566. With permission.)

With permission.)

Sultan et al. [16] investigated 202 pregnant women before and 6 months after delivery using anal endosonography, manometry, perineometry, and pudendal nerve terminal motor latencies. Thirty-two women had new abnormal postnatal findings (defects on endosonography or prolonged pudendal nerve terminal motor latencies). Ten of the 79 primiparous women (13%) and 11 of the 48 multiparous women (23%) who delivered vaginally had anal incontinence or fecal urgency when studied 6 weeks after delivery. Twenty-eight of the 79 primiparous women (35%) had a sphincter defect on endosonography at 6 weeks; the defect persisted in all 22 women studied at 6 months. Of the 48 multiparous women, 19 (40%) had a sphincter defect before delivery and 21 (44%) afterward. None of the 23 women who underwent CS had a new sphincter defect after delivery. The use of forceps was the single independent factor associated with anal sphincter damage, and there was a strong correlation with the presence of defects and the development of symptoms. This suggests that it is the first vaginal delivery that is the most important factor for damage to the anal sphincters. One criticism of this paper was the lack of blinding, and other authors have demonstrated that symptoms do not always correlate with ultrasound findings [101].

Forceps delivery results in more traumas to the anal sphincters and is associated with a higher incidence of defecatory symptoms than a ventouse delivery. Sultan et al. [11] found anal sphincter defects in 81% of women who underwent a forceps delivery compared to 24% of those who were delivered by ventouse and 36% of controls.

Subsequent studies have looked at the incidence of anal sphincter injury using endoanal ultrasound, and meta-analysis of five of these studies reveals a 26.9% incidence of anal sphincter injury in primiparous women and an 8.5% incidence of new sphincter defects in multiparous women. Overall, 29.7% of women with anal sphincter defects were symptomatic though 3.4% of women experienced postpartum fecal incontinence without a sphincter defect (Table 58.2) [96,102].

The use of episiotomy and its relationship to anal sphincter injury is unclear. Poen et al. [103] reported that the use of a mediolateral episiotomy was associated with fewer third-degree tears, and Sultan et al. [98] reported that almost half of these women who had sustained third-degree tears had undergone an episiotomy. The use of midline episiotomies, favored in the United States, has been strongly associated with a 50-fold increased risk of a third-degree tear [104]. This is reflected in the threefold increased risk of fecal incontinence following midline episiotomy versus a spontaneous perineal laceration, and so research remains divided as to the protective effect of a mediolateral episiotomy for OASIS (obstetric anal sphincter injury service). It is apparent from the published literature that even with nonmidline episiotomies, the risk of OASIS is strongly associated with the angle of incision of episiotomy [105]. Studies have demonstrated that there is little attention and much imprecision with regard to the angle of incision of mediolateral episiotomy [106]. Consequently, the inconsistent findings of research as to whether mediolateral episiotomy has a protective or influencing effect on OASIS could be due to the variation in actual position of the episiotomy incision. Until there is standardization among clinicians worldwide on the correct angle and position of a mediolateral episiotomy, whether or not it is a risk variable for OASIS will remain a matter of conjecture.

Table 58.2 Sphincter Defects and Symptoms: Meta-Analysis of Studies Reporting Obstetric Sphincter Damage

		No. of women for meta-analysis		No. of women with sphincter defect				
Reference	Total	Primip	Multip	Primip	Multip	Symptomatic defect (%)	Postpartum fecal incontinence but no new sphincter tear (%)	Follow-up rate (%)
Sultan et al. [11]	127	79	48	28	2 new (19 old)	20.4 (10 of 49)	1.3 (1 of 78)	100
Abramowitz et al. [126]	202	96	106	25	14 new	23.1 (9 of 39)	6.7 (11 of 163)	100
Varma et al. [127]	120	78	42	9	6 old and new	0	0	71.6
Fynes et al. [110]	118	59	59	20	2 new	68.2 (15 of 22)	0 (0 of 96)	100
Faltin et al. [128]	150	150	0	42	0	36.6 (15 of 41)	6.8 (7 of 103)	96
Overall	717				167 new and old, all women	32.5 (49 of 151)	4.3 (19 of 440)

Abbreviations:Multip, multiparae; primip, primiparae.

The degree of anal sphincter trauma may also be related to occurrence of symptoms. A questionnaire study of 208 women, 13 years after vaginal delivery, found that 25% of women after fourth-degree tears and 11.5% after third-degree tears complained of anal incontinence of gas, liquid, or solid stool [23]. In another American study [107] of 2858 primiparous women delivered vaginally, 19% were known to have sustained third- or fourth-degree tears. Although this study was limited in that it was questionnaire based and retrospective, it highlighted the high prevalence of anal sphincter tears possible, a reflection of the practice of midline episiotomy performed in the United States. The incidence of worse bowel control was 10 times higher in those with fourth-degree lacerations versus third-degree lacerations, which is not surprising as both internal and external sphincters are then compromised and as such cannot compensate so easily for the loss of function in the other. The urgency associated with internal sphincter damage may also exacerbate loss of bowel control to a greater degree. Another observation was that more than 50% reported new onset urinary incontinence indicating that similar risk factors pertaining to anal sphincter trauma may relate to damage and loss of function of the urethral continence mechanism.

There may also be an inherent predisposition to anal sphincter trauma as there are racial differences in incidence, with the incidence of trauma greater in Asian women versus white women versus with black women having a lower incidence. This suggests that there are anatomical or physiological predisposing factors [108]. Further evidence of genetic predisposition due to tissue types comes from a telephone survey of women who had undergone an instrumental delivery. This study reported that those with a history of joint hypermobility (a marker for collagen weakness) had an increased risk of postpartum anal incontinence [109].

Despite obvious injury to the anal sphincters, symptoms of anal incontinence may not occur for some time after delivery, and in women who experienced transient anal incontinence after a complete tear, 39% had a relapse of symptoms after the next vaginal delivery. The major long-term problem seen in these women was incontinence of flatus. Fynes et al. [110], in a study of women undergoing a second vaginal delivery, with a history of occult sphincter injury or transient fecal incontinence after their first delivery, found that there was a significant risk of these women having persistent fecal incontinence. Full-thickness anal sphincter disruption was the most significant risk factor in the development of fecal incontinence after a second vaginal delivery. However, other smaller studies have shown no significant change in anal incontinence or anal physiology in the short term for women with a previous obstetric anal sphincter injury following a subsequent birth [111].

CHILDBIRTH AND PROLAPSE

Genital prolapse occurs as a consequence of weakness of the fibromuscular supports of the pelvic organs. Although the etiology of genital prolapse is multifactorial, childbirth has been implicated as a major contributing factor. It is far more common in parous women, with 50% of parous women having some degree of genital prolapse, of which 10%–20% are symptomatic. In contrast, only 2% of symptomatic prolapse is found to occur in nulliparous women. The risk of prolapse is higher with increasing parity [112].

The mechanism of prolapse is unclear. Pathological and electrophysiological studies have shown that significant pelvic nerve denervation and reinnervation are associated with stress incontinence and prolapse. However, there are also collagenous changes in the pelvic floor, which are related to ageing, childbirth, and endogenous hormone changes, which may also predispose to prolapse and stress incontinence [113].

During vaginal delivery, the combination of distension and stretching of the pelvic floor by both the fetal head and increase in pressure due to maternal expulsive efforts may lead to functional and anatomic alterations in the muscles, nerves, and the connective tissue of the pelvic floor and anal canal. Trauma to the pelvic floor may also lead to repair with weaker collagen and so predispose to incontinence and prolapse. Prolapse is noted to be more common in women after a vaginal delivery compared to after a CS [114]. Using the POP-Q examination, O’Boyle et al. [115] found that the 23 nulliparous pregnant women had an increased POP-Q stage compared to 21 nonpregnant controls. An increase in POP-Q stage is also seen after vaginal delivery and this correlates well with increased mobility of the bladder base and neck [75]. These studies suggest that both pregnancy and delivery are important etiological factors for the development of pelvic organ prolapse.

The use of MRI and ultrasound has provided further insight to the ultrasound studies previously mentioned into pelvic floor dysfunction. Changes in the levator hiatus have been shown to be related to urogenital prolapse, and surgery for prolapse has been associated with a reduction in the size of the urogenital hiatus [116]. This suggests that a more distensible levator hiatus is associated with risk of pelvic organ prolapse. MRI has previously shown abnormalities in the levator ani in women with stress incontinence and prolapse. In one study [23] comparing nulliparous women and women after their first vaginal birth, 20% of primiparous women had a visible defect in the pubovisceral or iliococcygeal portion of the levator ani muscle. These defects were not seen in the nulliparae group. Those women with urinary incontinence were more likely to have a defect in the levator muscle. In another study, it was noted that increasing levator trauma was found in those with a longer second stage of labor. These defects are thought to be either due to avulsion of the muscles from their origin or as a result of denervation. However, whatever the possible mechanism, it is clear that such damage to the levator “plate” leads to a decrease in muscular supports to the pelvic organs and an increase on the load carried by the connective tissue and fascia. These injuries may themselves relate to stress incontinence or predispose to weakening of fascial and connective tissue supports resulting in stress incontinence.

Pelvic floor ultrasound has been an increasingly useful tool for revealing changes in the levator anatomy related to parity. Using translabial ultrasound, Dietz et al. reported that in a study of 68 nulliparous women during the third trimester and 2–6 months postpartum, vaginal delivery was shown to relate to an increased prevalence and size of a true rectocele (defect in the rectovaginal septum). These defects are associated with symptoms of pelvic organ prolapse and obstructed defecation (Figures 58.5 through 58.8) [117]. However, rectoceles were also seen in those after CS, so pregnancy itself may affect the integrity of the rectovaginal septum. In another study by this group, vaginal delivery was noted to be associated with avulsion of the levator ani from the pelvic side wall in one-third of women.

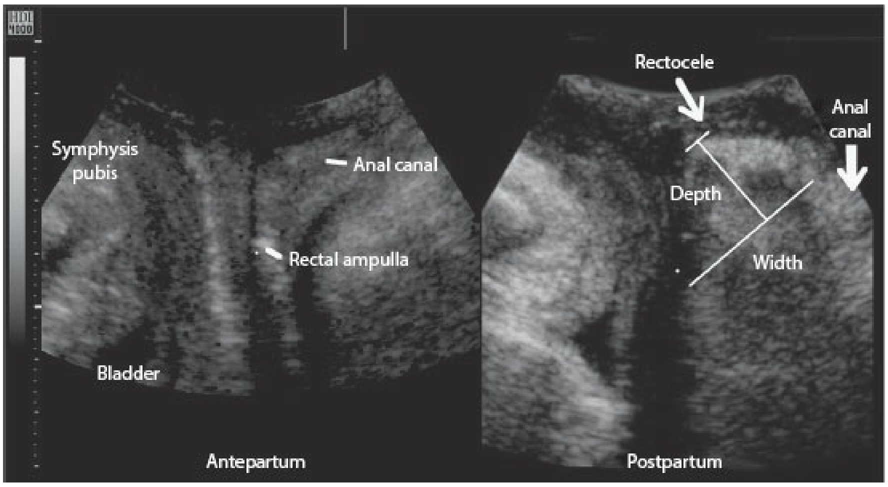

Figure 58.5 Comparison between posterior compartment imaging (midsagittal plane) in the third trimester (left) and 3 months postpartum (right) on maximal Valsalva maneuver. The anorectal junction appears normal on the left. On the right, there is a rectocele, with a depth of about 2 cm, filled with stool. (Reproduced from Dietz HP and Steensma AB, *Br J Obstet Gynecol*, 113, 264, 2006. With permission and by courtesy of H.P. Dietz.)

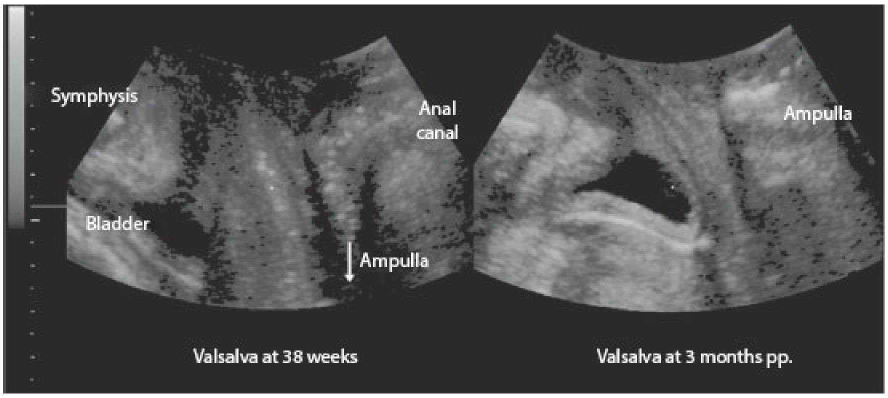

Figure 58.6 Comparison between posterior compartment imaging (midsagittal plane) in the third trimester (left) and 3 months postpartum (right), on maximal Valsalva. The anorectal junction is normal on the left. The right image shows increased bladder descent and perineal mobility, resulting in displacement of the rectal ampulla below the symphysis pubis. There is no actual rectocele, that is, no defect of the rectovaginal septum shown in Figure 58.5. (Reproduced from Dietz HP and Steensma AB, *Br J Obstet Gynecol*, 113, 264, 2006. With permission and by courtesy of H.P. Dietz.)

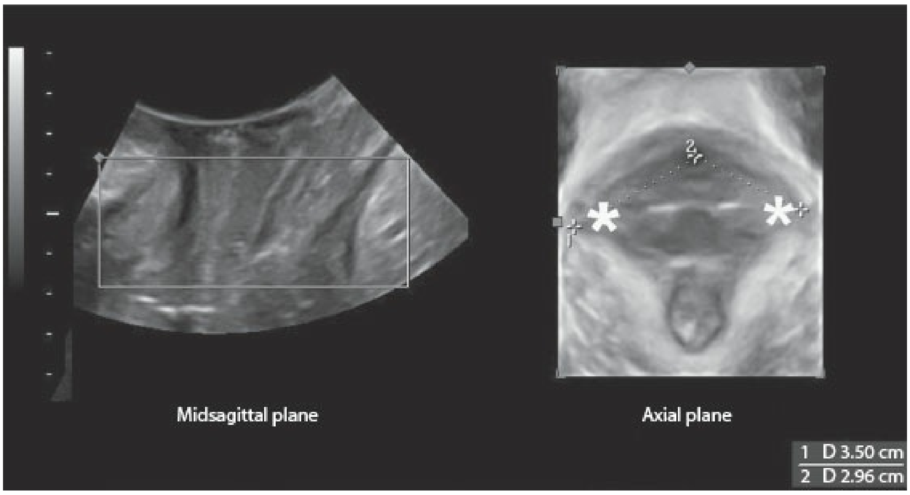

Figure 58.8 Typical bilateral avulsion injury seen in primiparous patient (forceps) as seen in the axial plane (right image). The defects are indicated by *. (Reproduced from Gamble, J.A. and Creedy, D.K., *Birth*, 27, 256, 2000. With permission and courtesy of H.P. Dietz.)

CONCLUSIONS

The development of pelvic floor disorders such as urinary and fecal incontinence and genital prolapse have been associated with pregnancy and vaginal delivery. Over the last two decades, histology, imaging, and physiological techniques have revealed mechanisms of injury to the pelvic floor, which include direct muscle trauma, disruption of connective tissue support, and denervation with the time of greatest risk of damage at the first vaginal delivery.

In recent years, there has been an ongoing debate regarding the protective effect of an elective CS in reducing the risk of pelvic floor disorders, and women are increasingly requesting CS for nonmedical reasons [130]. The debate is ongoing as the evidence supporting this is conflicting and much is derived from small studies of heterogenous cohorts with differing and inconsistent definitions of incontinence. Epidemiological studies implicate parity as associated with incontinence; however, it is less clear what specific association of mode of delivery has on incontinence. Less pelvic floor damage seems to occur after “elective” but not necessarily “emergency” CS. With regard to urinary incontinence, some data suggest that cesarean is protective; however, others suggest that it is pregnancy itself that is the major risk factor. Elective CS appears to prevent against mechanical trauma to the anal sphincter but not necessarily the urethral sphincter. However, elective CS is not wholly protective for anal incontinence [118]. In addition, it has been estimated that 167 cesarean deliveries are needed to prevent one case of fecal incontinence. Therefore, before considering these potential benefits of cesarean delivery, they must be weighed against the potential risks for the mother and child, including increased risk of postpartum hysterectomy, adhesions, ileus, placental implantation, problems in future pregnancies, and increased respiratory distress syndrome in the newborn [119,120]. An answer to this question would really only come with women randomized to either vaginal birth or elective CS, though this is, of course, impossible for clear ethical and practical reasons. However, these data are short term, and even if CS were in the short-term protective, this protective effect diminishes with time and subsequent deliveries and factors such as ageing, and the menopause may then be more relevant. A reanalysis of the EPINCONT study [121] has shown that women who have children at an older age are more likely to suffer from stress incontinence and this is supported by ultrasound studies, which show an increase in odds of levator trauma of 10% for each year of delayed childbearing [122]. These findings suggest that as women in Westernized societies delay childbearing, there will be a rise in the incidence of pelvic floor morbidity.

Given the lack of clarity with the present data, the focus should be on modifying potential risk factors that may impact on pelvic floor trauma. Women should be offered strategies to reduce pelvic floor injury and incontinence such as pelvic floor exercises, which have been shown to reduce urinary incontinence and increase pelvic floor strength [123]. Adequate training is required in recognition of perineal trauma and repair and intra- and postpartum bladder care. Consideration needs to be made of the experience and training of birth attendants as inexperienced birth attendants may increase perineal damage. Labor ward management should be reviewed with regard to choice and technique of instrumental delivery and use of episiotomy as it is known that even the angle and technique of the episiotomy can vary widely and may often be more midline than mediolateral in position. Easing the perineum with controlled delivery of the fetal head has also been shown to reduce the perineal trauma rate though this is often not used with the vogue for the “hands-off” approach employed by many birth attendants [124].

There are other modifiable factors that should also be addressed such as constipation and high body mass index, both of which were associated with an increased prevalence of urinary and anal incontinence [125]. It may be prudent to consider active programs to promote a healthy prepregnancy body mass index, not only for reducing pelvic floor morbidity but also for minimizing the risk of pregnancy complications including CS.

For those women in whom postpartum incontinence and prolapse develop, treatment strategies and follow-up should be readily available and standardized protocols developed. There are now clear guidelines indicating the relevant therapies and investigations that could be used in these situations. Long-term studies are required in assessing the outcome of interventions and treatments in women prior to and after delivery.

59 Problems Associated with Sexual Activity

Swati Jha

Female sexual dysfunction (FSD) is defined as a sexual desire, sexual arousal, orgasm, and/or sexual pain disorder that causes personal distress (Table 59.1). FSD is a relatively common health issue for women with a community prevalence of 30%–50% [1]. The wide range of the reported percentages depends on the impact of different concomitant factors on sexual function, such as interpersonal and emotional relationship, well-being, and psychological factors. Studies have shown that FSD and other sexual problems have been linked to a “diminished quality of life, low physical satisfaction, low emotional satisfaction, and low general happiness” [2]. Women’s sexuality and sexual function are very complex issues, strongly modulated by psychosocial situation, and this necessitates a biopsychosocial approach for understanding the basis of dysfunction. Physiological events, such as pregnancy, childbirth, menopause, aging, and gynecological conditions like infertility, prolapse, urinary incontinence (UI), and gynecological cancers, have an impact on sexual well-being. The interaction of these conditions with sexual health needs to be better understood to deal effectively with the problems as a whole.

Sexual dysfunction is highly prevalent in women attending urogynecological services with a prevalence of 50%–64% [3–5]. Furthermore, urogynecological surgery represents an important but underestimated cause of FSD. Different problems of the pelvic floor can impact sexual activity in different ways. Interest in and publications about FSD are very recent [3].

In this chapter, we review the correlation of common urogynecological conditions on sexual activity and the impact of their treatment.

URINARY INCONTINENCE

UI is a common condition and epidemiological studies suggest that it affects up to 41% of the adult female population [6]. It is a health burden and impacts social, psychological, occupational, domestic, physical, and sexual well-being [7–10]. Women reporting lower urinary tract symptoms (LUTS) or UI complain of a deteriorating quality of life (QoL) in terms of social and psychological problems and also of sexual dysfunctions in significantly greater numbers than the general healthy population, as reported in a recent cross-sectional study [11]. Table 59.2 shows the prevalence of UI during sexual activity as shown in different population groups.

Complaints of stress urinary incontinence (SUI), overactive bladder (OAB), and LUTS have a negative impact on all domains of sexual function [7,11]. In women with pelvic floor dysfunction, the symptoms per se, along with fear of odor, embarrassment, shame, loss of self-esteem, and fear of, or actual occurrence of, incontinence, are contributory factors. The most common sexual complaints in women with UI are low desire, vaginal dryness, and dyspareunia independent of age, educational attainment, and race [12].

Even in community-dwelling women aged over 55, 5% were not sexually active due to UI, and 25% of these sexually active women reported a negative influence of urine loss on their sex life [13].

In women with SUI, the prevalence of coital incontinence ranges from 11% to 70% [14–18]. Traditional teaching has been that urodynamic stress incontinence (USI) is associated with penetration incontinence and detrusor overactivity with orgasm incontinence [16]; however, subsequent studies by Moran et al. [17] have failed to confirm this association. In their observational study, USI was associated with high rates of penetration incontinence (80%), orgasm incontinence (93%), and a combination of the two (92%). Jha et al. [18] correlated different urodynamic diagnoses to orgasm or penetration incontinence and found no association.

Among the different types of UI, OAB has a particularly high association with sexual dysfunction in various studies [19–21], which could be indicative of an underlying psychosomatic disorder [22]. However, studies assessing the overall prevalence of sexual dysfunction in women with OAB and the impact on QoL remain controversial [23], whereas menopausal and partner status have been shown to be the better predictors [24].

Until recently, the impact of treating incontinence on sexual function has been controversial. Before the introduction of minimally invasive suburethral sling procedures, Burch colposuspension was regarded as the "gold standard" for the surgical correction of SUI. There are some data regarding the impact of colposuspension on sexual health. Moran et al. [25] evaluated 55 women with SUI who reported coital incontinence before undergoing colposuspension. Preoperative coital leakage occurred in 65% with penetration, in 16% with orgasm, and in 18% with both. After surgery, 81% of the women reported no coital incontinence. Baessler et al. [14] showed similar improvements in coital incontinence following a colposuspension.

The impact of midurethral slings, specifically tension-free vaginal tape (TVT) on female sexual function (FSF), has been unclear. Different studies have shown different outcomes, with some suggesting deterioration [26–29] of sexual function and some an improvement [30–32], whereas others were equivocal [33–36]. Deterioration in function may be associated with dyspareunia [29], loss of libido, or partner-associated discomfort. There have also been anecdotal reports of anorgasmia after TVT probably related to passage of the trocar and subsequent injury to the dorsal nerve of the clitoris [37]. However, there seemed to be a consensus that TVT reduces coital incontinence rates by between three- and sixfold [29,33,38].

Table 59.1 Classification of Female Sexual Dysfunction (DSM IV TR [Text Revision])

1. Sexual desire/interest disorders
2. Sexual arousal disorders

The obturator approach appeared to have an overall beneficial effect [37,39] on sexual function comparable to the retropubic approach (TVT) [40]. In a comparison of the outside-in and the inside-out technique, reports are conflicting with one study suggesting the inside-out technique (TVT-O) to be better [39] and another study showing the outside-in technique (TOT) to be superior [37].

Jha et al. [41] conducted a systematic review of all continence procedures and the impact of treating urinary incontinence on sexual function. They found that coital incontinence was significantly reduced following continence surgery. However, though the pooled results suggest between two and three times greater likelihood of improvement compared to deterioration in sexual function, at least half of all women undergoing surgery for stress incontinence are likely to experience no change in sexual function. There was no difference in sexual function following the two most commonly performed procedures for SUI, i.e., the TVT and TOT/TVT-O.

In sexually active women with OAB and concurrent sexual dysfunction, sexual QoL, Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire (PISQ) scores, and anxiety states were all improved with corresponding improvement in OAB scores by treatment with anticholinergics [42,43]. Treatment of OAB has also been shown to improve with both percutaneous tibial nerve stimulation [44] and sacral nerve stimulation too [45].

PELVIC ORGAN PROLAPSE

Pelvic organ prolapse (POP) is a common medical problem in parous women and particularly with advancing age. As life expectancy increases, this is acquiring greater significance, and 20% of women on gynecology waiting lists in the United Kingdom are awaiting prolapse surgery, demonstrating the enormity of this virtual pandemic. The incidence of prolapse requiring surgical correction in women who have had a hysterectomy is 3.6 per 1000 person-years of risk, the cumulative risk of prolapse being 1% at 3 years and 5% at 17 years after a hysterectomy [46].

Table 59.2 Studies Showing Prevalence of Urinary Incontinence during Sexual Intercourse

Authors	**Design and setting**	**Symptoms analyzed**	**% with UI during intercourse**

A review of literature shows conflicting results on the impact of prolapse on sexual function, with some studies showing a deterioration of function and others showing no impact [12]. In their observational study, Handa et al. interviewed 1299 participants and 495 (38.1%) had evidence of pelvic floor disorders. Sexual complaints were significantly more common among women with pelvic floor disorders (53.2% vs. 40.4%, $p < 0.01$), and compared to UI, POP was not associated with any sexual complaint. A study by Weber et al. [47] examined 80 women with prolapse and compared their continence status; they also included 30 controls (women with no prolapse). The study showed no difference in global sexual function score, vaginal dryness, dyspareunia, interest in sexual activity, or satisfaction with their sexual relationship. They concluded that women with prolapse and UI do not differ from continent women without prolapse in measures of sexual function, and age is the most important predictor of sexual function. Burrows et al. [48] came to similar conclusions in their retrospective study of 352 women with prolapse. They also found that prolapse severity did not impact on sexual function. The study by Barber et al. [49] comparing the impact of prolapse and incontinence on sexual function found completely the opposite results. In their review of 343 community-dwelling women with either symptomatic prolapse or incontinence, they found that prolapse was more likely to influence sexual function than UI. This study also demonstrated that treatment of prolapse was less likely to impact on change in sexual function, whereas treatment of incontinence resulted in a mild improvement in sexual function.

Other studies have shown that prolapse causes several problems with sexual function including discomfort, UI (40%) (both orgasm and penetration), obstruction, and dryness during intercourse.

Women with prolapse were more likely to have urinary and/or fecal incontinence during sexual activity, more dyspareunia, and fewer orgasms. They were also more likely to report negative emotional reactions associated with sex and higher rates of embarrassment leading to avoidance of sex [50]. Presence of both prolapse and incontinence has a cumulative negative effect on sexual function, with libido, sexual excitement, and orgasm being significantly affected. The increasing severity of prolapse is associated with symptoms related to UI, voiding, defecation, and sexual dysfunction that do not necessarily correlate with the location of prolapse and therefore are not compartment-specific [51].

Some explanation of the differences in these findings is that assessment of the impact of POP and UI on sexual function is difficult because of the following:

1. Different tools have been used in different studies.
2. Studies cluster prolapse and incontinence under the same umbrella.
3. Study groups are small.
4. Different types of prolapse clumped together (different compartments, different grades).

As a result, the multitude of studies report on the impact of prolapse surgery on sexual function, but the results are very conflicting with some being equivocal reporting no impact of prolapse correction on sexual function and others demonstrating a deterioration of sexual function following prolapse treatment. The cause of sexual dysfunction following vaginal surgery may be classified as organic and/or psychosocial [52]. Organic causes are anatomical, physiological, vascular, neural, and hormonal. Psychosocial factors on the other hand such as life stressors, anxiety, and depression must be borne in mind. Altered perception of genital health after surgery, both by the woman and her partner, with associated apprehension and fear of damage to the internal organs, can also be contributory factors for a negative impact on sexual function.

The verdict is still open on the impact that prolapse has on sexual function, and larger epidemiological studies with careful assessment and agreement of the tolls used to assess impact are required to substantiate or refute the currently available conflicting evidence. This will also be partly achieved by the long-term follow-up of randomized controlled trials. When counseling women with a prolapse and particularly before treatment, these factors should be featured in the discussion and aid decision-making. This allows more realistic expectations from the treatments available and avoids disappointment when those goals are not met. There remain many unanswered questions, but it is important to remember that the presence of anatomical defect does not imply dysfunction. The goal of pelvic surgery should be restoration of anatomic support without deleterious effects on visceral and sexual function. Data are currently limited on QoL and sexual function following both traditional and graft-reinforced anterior vaginal prolapse surgery; further research is required to determine whether surgical technique and type of graft used impact surgical outcome and complications before introduction into routine clinical practice. Women should be counseled and managed depending on current best available evidence.

Current treatment options for vaginal wall prolapse include pelvic floor muscle training (physiotherapy), use of topical hormone replacement therapy (HRT), use of mechanical devices (ring or shelf pessaries), and surgery, with or without mesh reinforcement. The impact of these different forms of treatment for prolapse on sexual function is discussed here.

Physiotherapy

In their systematic review looking at the benefits of pelvic floor muscle training (PFMT), Hagen et al. [53] identified some benefit on sexual function in women with mild prolapse. But even more reassuringly, women who were currently performing PFMT scored significantly better on several aspects of sexual function [54,55] and PFMT is therefore to be encouraged in women.

Estrogen Therapy

There are no studies looking at the impact of estrogen therapy in women with prolapse or its impact on sexual function. However, several studies have shown an individual improvement in symptoms of atrophic vaginitis that [56] may negatively impact sexual function even in the absence of prolapse; hence, it may be considered for that indication.

Pessaries

There are a variety of pessaries available, made of rubber, plastic, or silicone-based material. The commonest pessaries are the rings and shelf, but other types being increasingly used are the inflatable, the doughnut, and the Gellhorn, all of which have slightly different uses and specifications. A recent study by Kuhn et al. [57] demonstrated that desire, lubrication, and sexual satisfaction significantly improved with pessary use, though orgasm remained unchanged (Figure 59.1).

A comparison of sexual function in women with pessaries or surgery [58] for the treatment of POP found a significant improvement in sexual function in both groups though there was increased frequency of intercourse in the surgery group (54% vs. 46%; $p = 0.028$), which was not significant when controlled for age.

Lowenstein et al. [59], on the other hand, found greater improvement following surgery than use of pessaries, and this appeared to be related to altered self-perceived body image.

Surgery

Richard TeLinde said, “Every surgeon of extensive and long experience will have to admit that he is not entirely and absolutely satisfied with the long-term results of all his operations for prolapse and allied conditions,” and this is further substantiated by the further surgery rates for recurrent prolapse being in the region of 30% [60]. White in 1908 said, “Plastic gynaecology remains the last unsolved problem of surgical gynaecology,” and this remains true even in the twenty-first century.

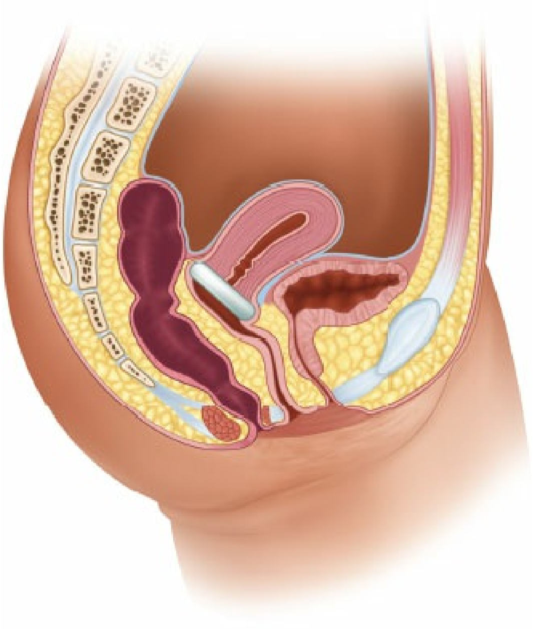

Figure 59.1 Ring pessary in situ: no interference with sexual activity.

Surgical correction of prolapse depends largely on the compartment that is affected. So for vaginal wall prolapse, it may involve an anterior colporrhaphy/anterior vaginal wall repair, posterior colporrhaphy/posterior vaginal wall repair, or a vaginal hysterectomy. For a vaginal vault prolapse, surgical correction may require sacrospinous fixation, an abdominal sacrocolpopexy, or infracoccygeal procedures that may involve the use of trocar systems (which at the time of writing included, e.g., Apogee, Post I-Stop).

Though Weber et al. [35] identified a decrease in the vaginal dimensions after surgery for prolapse, this was associated with either no alteration in sexual function or a mild improvement. This may be related to a change in vaginal dimensions during arousal and intercourse. Dua et al. had similar conclusions following anterior or posterior repair [61]. When an anterior repair was combined with a posterior repair, anterior vaginal repair does not appear to impact adversely on postoperative sexual function or cause dyspareunia. Nevertheless, there are very few data confirming this paradigm. Weber [62] compared three surgical techniques for cystocele repair; the dyspareunia rate reduced from 30%

preoperatively to 22% postoperatively.

An anterior repair (with or without a vaginal hysterectomy) for prolapse does not impact adversely on sexual function [61,63]. Both Colombo [64] and Van Geelen [65] found that anterior repair when compared to a Burch colposuspension for a cystocele did not predispose to dyspareunia. Though it was associated with significant vaginal shortening when compared to the Burch, this did not appear to impact on function unless combined with a posterior repair.

Combining a posterior vaginal wall repair with anterior colporrhaphy may however increase dyspareunia rates, and there may be a place for doing the two procedures separately where feasible. This would also indicate that a prophylactic posterior repair should be avoided at the time of an anterior repair in sexually active women. This was also shown in the study by Dua et al. [61].

Studies looking at posterior vaginal wall defect are more confusing, and whereas earlier studies suggest dyspareunia and problems with intercourse [66] with a posterior repair, this is not substantiated in more recent studies and this could be due to a recognition of the problem and a change in technique [67]. Levator ani plication is frequently implicated as the cause for dyspareunia due to postoperative midvaginal narrowing [66,68,69]. In contrast, improvement in dyspareunia has been reported with site-specific defect or midline plication procedures [70–72]. In sexually active women, therefore, levator plication should be avoided where possible and surgical techniques aimed at avoiding narrowing of vaginal introitus/mid vagina be adopted.

Vault prolapse surgery may be associated with postoperative dyspareunia and FSD. However, as this procedure often involves a concomitant repair, it is methodologically difficult to ascertain which specific procedure is causing sexual dysfunction. Maher et al. [73], in their systematic review comparing sacrocolpopexy to sacrospinous fixation, showed lower dyspareunia rates with the abdominal approach but a longer operating time, a longer time for recovery, and a greater expense. Baessler and Schuessler found that sacrocolpopexy was actually curative in women with dyspareunia and ceased in all but one of the nine patients among 33 consecutive women presenting with prolapse-related dyspareunia preoperatively [74]. Postoperative dyspareunia is reported to be between 8% and 16% after sacrospinous fixation [75–77]. When combined with a repair vaginal narrowing, excessive colpectomy occurring due to concomitant repair procedures was identified as the most common cause of postoperative dyspareunia [78], but vaginal narrowing and pudendal nerve injury have also been implicated. A sacrocolpopexy has also been shown to be superior to a vaginal mesh with lower extrusion rates and less impact on sexual function [73]. Kuhn et al. [79] demonstrated that following a sacrocolpopexy, the domains of sexual desire, arousal, lubrication, satisfaction, and pain improved significantly but orgasm remained unchanged. There was no vaginal shortening postoperatively. Therefore, in sexually active women, a sacrocolpopexy is the preferred procedure.

Iliococcygeal fixation is also performed for vault prolapse. In a matched case–control study comparing sacrospinous to iliococcygeal fixation, Maher et al. [80] found no significant difference in the percentage of women who were sexually active (58% vs. 55%), had dyspareunia (14% vs. 10%), or had buttock pain (19% vs. 14%). It is well recognized that bilateral iliococcygeal fixation may result in shortening of the vagina by 2–3 cm. In sexually active women with vault prolapse and a short vagina, bilateral iliococcygeal fixation is contraindicated, as it may cause severe postoperative dyspareunia.

Mesh

The aims of using mesh in the repair of vaginal wall prolapse are to add additional support and to reduce the risk of recurrence, particularly for women with recurrent prolapse or with congenital connective tissue disorders (such as Ehlers–Danlos or Marfan’s syndromes). A study by Abdel-Fattah et al. [81] looking at the complications of mesh reinforcement identified some very severe complications and therefore the need for caution when using synthetic materials in the absence of clear-cut indications. Further reports on problems with the use of meshes have resulted in a distinct decline in mesh usage with the commonest cause of complaints following mesh-reinforced repair according to the FDA report of 2011 [82,83] being pain or dyspareunia (590/1503, 38.6%). This has resulted in withdrawal from the market of some of the products including those by Bard and Ethicon.

Some studies have shown unacceptably high dyspareunia rates following mesh reinforcement for prolapse surgery. Milani et al. [84] demonstrated that though the use of mesh was associated with high success rates, there was a very high rate of dyspareunia of 20% when used for anterior repair and 63% when used for posterior repair. This warrants extensive counseling and caution when using meshes in women who are sexually active. These results are further borne out by other studies though some studies are equivocal and some even demonstrate an improvement following the use of mesh in vaginal repair.

Maher et al. in their systematic review [73] analyzed sexual function and dyspareunia in women undergoing surgery in the anterior compartment, posterior compartment, and apical compartment using mesh. The studies included in their systematic review were women who had mesh-reinforced colporrhaphy versus standard repair. Interestingly in contrast, the FDA report found no difference in the dyspareunia rates for native tissue anterior or posterior repair and mesh-reinforced anterior or posterior repairs.

URINARY TRACT INFECTIONS

The association of LUTS and sexual dysfunction is widely accepted. The incidence of urinary tract infections (UTIs) in women who are sexually active is about 3% per annum and about 4% of all LUT infections in this group are thought to be related to sexual activity and 60% in recurrent cases [85]. Honeymoon cystitis refers to LUTS occurring after initiation of sexual activity for the first time. Bacteria may be pushed mechanically up the urethra and into the bladder during coitus. Another hypothesis is microabrasions caused during intercourse, increasing the access of bacteria to the urinary tract. If they are not voided soon after, they multiply and may cause infection. The relative risk of UTI increased from 1.0 for unmarried women who had not been sexually active in the previous week to 9.0 for women who had had intercourse seven times during that period [86]. The term “honeymoon” was applied because, in the past, this was expected to be the time of first intercourse. The male urethra, being substantially longer, is not susceptible to the same problem. Some women are particularly sensitive to postcoital urinary tract dysfunction and this may be due to the development of a relatively high urethral pressure following intercourse. Of course, the condition of postcoital female lower urinary tract infection occurs at many times beyond the traditional “honeymoon”—from the onset of sexual activity into old age. This is further illustrated by the fact that nuns have a lower prevalence of bacteriuria than other populations of women in early adult life [87]. Following intercourse urinary bacterial count is significantly raised in 30% of women [88] and Nicolle et al. [89] reported that both symptomatic and asymptomatic bacteriuria were more frequent the day after intercourse. Several behavioral factors have been shown to enhance the risk of UTI following sexual intercourse. These include deferred voiding after intercourse [90], frequent intercourse [85], low fluid intake [91], and deferred voiding after the initial urge to micturate [92]. In addition, reduced lubrication and the use of spermicide-coated condoms and spermicides either alone or in conjunction with diaphragm have also been incriminated [93]. Contraceptive diaphragms by reducing urinary flow and spermicidal cream and the use of spermicidal-lubricated condoms can sometimes result in vaginal and urethral irritation, hence the association. These risk factors were shown to have a detrimental effect in the causation of UTI in a large prospective study by Hooton and coworkers who examined a variety of risk factors for UTI in young women [94].

The initial management of postcoital UTIs includes several simple measures that may be effective. Close attention to perineal hygiene, change of coital technique, use of a vaginal lubricant, and avoidance of the contraceptive diaphragm may all be successful first-line measures. Women should be encouraged to drink fluid before anticipated sex to facilitate postcoital voiding. Ingestion of products containing high-dose cranberry (as juice or a supplement) has long been thought to afford protection against UTIs [95]. Cranberries contain two substances (proanthocyanidins and fructose) that are thought to inhibit adhesion of infecting bacteria, particularly type 1 and type P fimbriated *Escherichia coli*, to the uroepithelium [96]. A systematic review of the literature considered the role of cranberry in the setting of recurrent UTIs and found the relative risk of developing a UTI over 6 months while taking cranberry to be reduced to 0.61 (CI 0.4-0.91) compared to 1.0 for placebo or no treatment [97]. The role of cranberry in prophylaxis against infection following intercourse, however, has yet to be established.

For women who do not respond to simple measures, regular or intermittent antibiotic prophylaxis is usually effective [98,99]. A recent systematic review of the literature found evidence that in women with recurrent UTIs associated with sexual activity, postcoital ciprofloxacin is equally as effective as a continuous daily prescription and should be considered in this setting [100]. There is evidence that local application of estrogen could be protective against infection in the context of recurrent UTIs in young women who are on oral contraceptives [101]. When simple measures fail to alleviate postcoital cystitis, further investigation including investigation for atypical organisms, such as *Mycoplasma hominis* and *Ureaplasma urealyticum*, is often worthwhile. Chlamydia causing acute urethritis should also be ruled out. Underlying abnormalities, such as voiding difficulties and vesicoureteral reflux, should always be considered and imaging of the renal tract with ultrasonography, intravenous urography, or videocystourethrography may be necessary. It is also sometimes appropriate to perform a cystourethroscopy and/or magnetic resonance imaging to exclude a urethral diverticulum or an intravesical foreign body such as a calculus.

BLADDER PAIN SYNDROME

Bladder pain syndrome (BPS), previously known as interstitial cystitis/painful bladder syndrome (IC/PBS), is a chronic, debilitating disease of unknown etiology characterized by urinary frequency, urgency, nocturia, suprapubic pressure, and pain. The true prevalence of the condition ranges from 10 to 500 cases/100,000 women depending on the strictness of the criteria used for the diagnosis [102,103]. Studies suggest that most women with IC have pelvic pain that extends to include dyspareunia and as a consequence sexually related distress; this in turn leads to a significant decline in desire and orgasm frequency [104–108]. The prevalence of sexual dysfunction in these women is higher than previously estimated and substantially affects QoL and sexuality [109]. Sacco et al. [106] showed that BPS was associated with the greatest impairment of FSF among women with LUTS. Because multiple factors contributing to sexual dysfunction (including biopsychosocial comorbidities such as stress, abuse, or chronic illness) can be present in women with IC, a variety of treatment approaches may be required. It is also important to recognize that some typical IC treatments, such as antidepressants and opioids used to manage pelvic pain, can exacerbate sexual dysfunction. Hypertonic pelvic floor dysfunction is prevalent in patients with IC [105] and contracted muscles can result in dyspareunia, vulvodynia, and vaginismus. The association between IC and syndromes such as vestibulodynia and spontaneous or provoked vulvodynia is commonly reported [110]. The magnitude of the association between vulvar and bladder symptoms is variable. This has obvious negative implications on sexual function, and sexual functioning is in fact one of the strongest predictors of poorer QOL in patients diagnosed with refractory IC/PBS [111].

Several studies have demonstrated an improvement in the dyspareunia and other levels of sexual function when PBS symptoms are alleviated either by intravesical injections of lidocaine, heparin, and sodium bicarbonate [112] or other pharmacological treatments [113] such as pentosan polysulphate and hyaluronic acid [114]. The pelvic floor muscles play an important role in female responsiveness and sexual function; thus, therapies aimed at treating the pelvic floor might be even more efficacious in improving sexual function, the woman’s self-esteem, and her relationship with her partner. Some therapies that have been reported to be helpful include pelvic floor therapy, biofeedback, neuromodulation, and botulinum toxin type A [115].

FECAL INCONTINENCE

Anal incontinence (involuntary loss of solid, liquid, or flatus) is reported to affect 8% of women in the general population [116]. Fecal incontinence (FI) (involuntary loss of solid or liquid) is known to cause sexual dysfunction, and this may be associated with anal sphincter injury related to birth trauma [117,118] or due to other causes such as neurological disorders. Fecal incontinence of solid stool and depression related to FI were correlated with poorer sexual function but do not prevent women from engaging in sexual activity thereby demonstrating that it is an important aspect of their lives [119].

Corrections of FI irrespective of the mode of repair were associated with an improvement in sexual function in most studies [118,120]. But patients who had undergone an overlapping sphincteroplasty versus an end-to-end sphincteroplasty reported pain during intercourse in 24% vs. 4% of subjects ($p = 0.04$). Sacral nerve stimulation, which is increasingly being used for the treatment of FI, has been shown to be of benefit [121,122]. However, some studies actually suggest an equivocal impact on sexual function following a repair [123]. Trowbridge [124] in his study showed that sexual function scores were not correlated with continence scores.

PREGNANCY CHILDBIRTH AND PERINEAL TRAUMA

Data on the impact of childbirth on sexual function are conflicting. There is a dearth of scientifically reliable data about the impact of childbirth on sexual function and the association with the different modes of delivery.

It is generally accepted that pregnancy itself is associated with reduced interest in sex, ranging from 57% to 75% [125–129]. Sexual interest usually improves postpartum but 23%–57% of women still report reduced sexual interest at 3 months and 21%–37% at 6 months [126,130]. Generally speaking, women are less likely to be sexually active during pregnancy, particularly in advanced pregnancy [126], with only 26% having intercourse in the third trimester. This could be due to a reduction in the ability to reach orgasm with 60% of women experiencing orgasm through the second trimester [127], declining to 50% in the third trimester [126]. Sexual function, which declined through pregnancy, was not recovered postpartum ($p = 0.017$). The main predictor for poor sexual function in early pregnancy was impaired body image, while in the postpartum period, worse urinary symptoms correlated with poor sexual function scores [131]. Interestingly, though sexual practices changed during pregnancy, they returned to early pregnancy levels in the postpartum period.

It is widely reported that postpartum dyspareunia is associated with the mode of delivery with assisted vaginal delivery being predominantly incriminated [118,132–134] with at least a twofold increase in dyspareunia when compared to spontaneous vaginal delivery. Barret et al. reported that women who delivered by cesarean section (C/S) were significantly less likely to report dyspareunia at 3 months postpartum than those with vaginal delivery [130]. However, the same authors in a subsequent study, by employing a larger cohort with longer follow-up, found that dyspareunia was equivalent in both groups [135]. This has been further substantiated in other studies that have failed to show that a C/S has a protective effect on sexual function [136,137]. With regard to vaginal delivery, however, a study by Buhling et al. [138] found the highest dyspareunia after operative vaginal delivery and least with elective C/S, which decreased uniformly in each group by 6 months. Operative vaginal deliveries had a persistent rate of dyspareunia of 14%, but there was no difference between the spontaneous vaginal delivery group with an intact perineum and C/S (3.4% dyspareunia at 6 months). Interestingly, at 3 months postpartum, all of the patients reported “enjoyment at sexual intercourse” regardless of the mode of delivery [138]. Perineal trauma with or without operative instrumental delivery was an important precursor of dyspareunia, and the greater the tear even, with spontaneous vaginal delivery, the lower the sexual desire [139,140]. Women with an intact perineum or first-degree perineal tear 6 months postpartum were more likely to experience orgasm [118] than those with a greater degree of perineal injury.

Postpartum, sexual desire and the ability to reach orgasm do improve, but the main problems encountered and impacting on sexual function are sexual arousal, excitement, and lubrication [130]. The risk of vaginal dryness and lubrication problems is increased with prolonged breastfeeding, which results in vaginal atrophy secondary to hypoestrogenism. The latter is easily corrected with topical estrogens or nonhormonal lubricants.

Owing to the inconsistencies in the definition of FSD and use of heterogeneous and invalid tools for evaluation in most of the studies, it is difficult to draw a scientifically consistent conclusion about the impact of mode of delivery on sexual health. Reports on the negative effect of vaginal childbirth on sexual health led to the concept of elective C/S to preserve sexual function. Many health-care professionals also advocate this approach with 7%–24% of obstetricians and 4.4% of midwives preferring elective C/S for themselves or their partner [141–143]. Interestingly, urogynecologists scored even higher, with 45.5% opting for primary elective C/S [143].

HYSTERECTOMY

Hysterectomy is the commonest major gynecological operation in the United Kingdom. Theoretically, it poses a risk not only to the intricate pelvic nerve plexus and damage to the autonomic nerve endings of the cervicovaginal fascia, hence impacting on orgasm or sensation during intercourse, but may also cause distortion of pelvic anatomy by shortening the vagina thereby resulting in dyspareunia. Historically, the uterus, “hystero,” was believed to be the center of female sexuality and may also have culture-dependent psychological effects leading to loss of self-esteem, female identity, and consequent FSD.

Following hysterectomy, an overall improvement [144] in the different aspects of sexual function, i.e., frequency of sexual relations, dyspareunia, orgasm, vaginal dryness, and sexual desire, was noted. The route of hysterectomy appears to play no role. A prospective study by El-Toukhy et al.

[145]compared hysterectomies performed abdominally, vaginally, or laparoscopically found that patients reported significantly lower rates of deep dyspareunia (18.8%, 19.7%, and 26.3% reduction, respectively) after surgery than before the operation, regardless of the routes and technique used. This was not substantiated in the study by Ayoubi et al. [146], who found greater postoperative delay in resuming sexual activity after abdominal hysterectomy (62.4 ± 9.3 days) than after vaginal (45.2 ± 6.7 days) hysterectomy. They also found that deterioration of sexual function occurred more frequently after abdominal hysterectomy (24%) than after vaginal (13.5%) or laparoscopic (8.5%) hysterectomy.

The belief that the cervix is necessary to achieve orgasm or that total abdominal hysterectomy (TAH) leads to local innervation damage with subsequent impairment of sexual function is not supported by current evidence. This belief was held for several years following a study by Kilkku et al. that found that women had a lower libido and orgasm following a TAH [147] when compared to a STAH. However, the same group subsequently reported an improvement in dyspareunia rates irrespective of the type of hysterectomy. Subsequent larger studies specifically comparing subtotal abdominal hysterectomy (STAH) and TAH [148] have also failed to identify a difference in sexual function. A study [149] looking at the long-term follow-up of women following a vaginal hysterectomy versus a Manchester Fothergill repair showed no difference in sexual function between the two groups, which further dispels this myth.

CONCLUSION

In spite of the common presentation of sexual dysfunction in association with pelvic floor disorders, overall assessment by clinicians remains low, and a recent survey of the members of the British Society of Urogynaecology (BSUG) demonstrated that only half of all clinicians routinely asked about FSD in the clinic and similar numbers at the postoperative follow-up visit [5]. Similar trends have been seen among the U.S. clinicians, and a recent survey of members of the American Urogynecologic Society (AUGS) has shown that 77% and 76% of AUGS members enquired of FSD, respectively, in similar situations [150]. Lack of time, uncertainty about therapeutic options, and older age of the patient were cited as potential reasons for failing to address sexual complaints as part of routine history. Clinicians dealing with women with these conditions need greater training to manage FSD in association with the underlying pathology.

Currently available evidence of pelvic floor problems and their impact on sexual function is conflicting. Greater and more robust research into different urogynecology conditions impacting on sexual function and their treatment is required. Assessment of patients with urogynecology problems not only requires a history and direct enquiry into sexual function, but also requires the development of standardized tools with well-defined end point to assess the severity of the problem. Broadly speaking, however, there is a body of evidence presented that treating pelvic floor conditions at worst does little harm and at best may significantly help. The aim now should be to increase awareness among clinicians to try and raise standards relating to this particularly as FSD may be an important part of individualized goal setting and treating what is important to patients.

60 Menopause

Timothy C. Hillard

INTRODUCTION

The menopause is a biological event unique to humans. The average age of the menopause in western women is approximately 52 years, so with women living well into their 80s, they can now expect to live over a third of their life in the postmenopause. Consequently, over the last 50 years, there has been an increasing interest in the effects of the menopause on long-term health, its effects on quality of life, and its potential treatments. In evolutionary terms, the menopause was considered advantageous as it allowed women who were no longer fertile to look after their children's offspring and allow their children to continue breeding—the so-called grandmother effect. The increasing use of grandparents as childminders to allow the mother to return to work could be considered a modern adaptation.

DEFINITIONS

The term "menopause" means the final menstrual period (from the Greek *menos*, month; *pausos*, ending). It occurs as a result of loss of ovarian follicular activity leading to a fall in estradiol levels below the level needed for endometrial stimulation. Strictly speaking, it can only be said to have occurred after 12 consecutive months of amenorrhea. While the menopause can sometimes be a sudden event, for most women, there is a gradual change in menstrual pattern in the years preceding the menopause as ovarian activity fluctuates, which may be accompanied by troublesome symptoms; this is often called the "perimenopause." The menopause, or final menstrual period, represents a watershed in the reproductive life of a woman as represented in the staging system originally described by the American Society for Reproductive Medicine and updated at the Stages of Reproductive Aging Workshop (STRAW +10) (Figure 60.1) [1].

The term "climacteric" is often used synonymously with perimenopause but means the phase of transition from the reproductive to the nonreproductive state, the menopause being a specific event within that phase. It is recommended that the term now be abandoned in clinical practice to avoid confusion [2].

A surgical menopause occurs when functioning ovaries are removed such as at hysterectomy for malignancy or severe endometriosis. A menopause may also be iatrogenically induced by other treatments such as radio- or chemotherapy for malignancy or temporarily during treatment with gonadotropin-releasing hormone (GnRH) analogues for a variety of conditions.

A "premature" menopause occurs if the menopause happens before the age of 45. This may occur naturally, be induced following surgery or other treatments, or be for other reasons (see Table 60.1). Women who have had a premature menopause are at an increased risk of a number of complications later in life and need special support.

ETIOLOGY

The ovaries produce three principal steroid hormones, estradiol, progesterone, and testosterone, although the latter plays no part in menstrual cycle control. Ovarian function and the normal menstrual cycle are controlled by the gonadotropins, follicle-stimulating hormone (FSH), and luteinizing hormone (LH), which are released from the anterior pituitary gland. Their release is controlled by the release of GnRH from the hypothalamus, which in turn is governed by the negative feedback from circulating levels of estradiol, progesterone, and inhibin (a peptide hormone produced by the ovary).

A detailed description of reproductive physiology can be found elsewhere [3]. In summary, each ovary contains several million germ cell units (oocytes), which achieve maximal levels in utero. There is a steady decline in these units over the prepubertal and reproductive years, but the maturation of these follicular units during this time is one of the key components of ovulation, corpus luteum formation, and ovarian steroidogenesis. It is estimated that up to 1000 follicles fail for every one that matures to ovulation (Figure 60.2). As the ovary ages, the remaining follicles, which are probably the least sensitive to gonadotropins, are increasingly less likely to mature and so ovulation declines and ovarian function gradually fails. Eventually, the level of estradiol production is no longer sufficient to stimulate endometrial proliferation and menopause ensues. Further decline in estradiol levels over subsequent years has effects on all estrogen-responsive tissues (which are widespread throughout the body—see Table 60.2). As a result, the effects of ovarian failure are often noted before the last period and the effects can go on for many years. Menopause may only be a single event, but it represents a significant change in a woman's hormonal milieu, which has implications for her future health and quality of life—hence the importance of postreproductive health for women.

The mean age of menopause in the Western world is around 51–52 years and has been so since Greek times [4]. There are significant variations around the world with some African and Asian communities reportedly having younger menopause [5]. Certain genetic and environmental factors may influence age of menopause such as growth restriction in utero, low weight gain in infancy, and poor nutrition in childhood and family history [6]. Smoking may reduce the age of menopause by up to 3 years and women with Down's syndrome are also more likely to have an early menopause.

	Menarche					FMP (0)				
Stage	−5	−4	−3b	−3a	−2	−1	+1a	+1b	+1c	+2
Terminology	**Reproductive**				**Menopausal Transition**		**Postmenopause**			
	Early	Peak	Late		Early	Late	Early			Late
					Perimenopause					
Duration	Variable				Variable	1–3 years	2 years (1+1)		3–6 years	Remaining lifespan
Principle Criteria

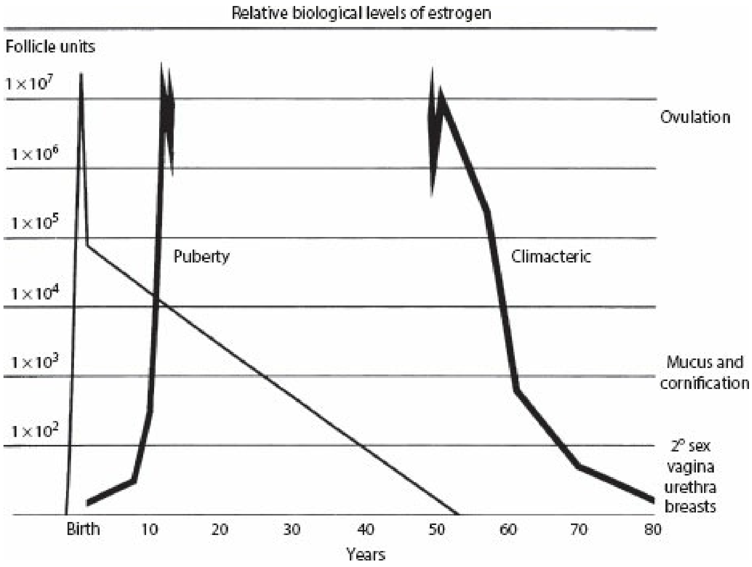

Figure 60.2 Correlation of follicle maturation, follicle availability, and estrogen production. (From Speroff L et al., *Clinical Gynecologic Endocrinology and Infertility*, Williams and Wilkins, Baltimore, MD, 1990, pp. 121–164. With permission.)

Table 60.1 Causes of Premature Ovarian Failure

Primary
Chromosome anomalies (e.g., Turner's syndrome, fragile X)
Autoimmune disease (e.g., hypothyroidism, Addison's disease, myasthenia gravis)
Enzyme deficiencies (e.g., galactosemia, 17-α-hydroxylase)
FSH receptor gene polymorphism
Secondary
Surgical menopause after bilateral oophorectomy
Chemotherapy or radiotherapy
Infections (e.g., tuberculosis, mumps, malaria, varicella, HIV)

A premature menopause (now called premature ovarian insufficiency) occurs in about 5% of women under 45, 1% of women under 40, and 0.1% under 30. It is one of the commoner causes of primary and secondary amenorrhea and should always be considered in the diagnosis. The implications of this endocrine failure can be very significant particularly at a young age. The cause of spontaneous premature ovarian failure is usually unknown, but there are a number of well-established causes that should be excluded (Table 60.1). Either there may be something wrong with the ovaries themselves (primary ovarian failure), e.g., certain chromosomal abnormalities or autoimmune disorders, or something happens to the ovary, e.g., oophorectomy, radiotherapy, or chemotherapy damage or infection.

INVESTIGATIONS

When to Investigate

Usually, the diagnosis of menopause is straightforward and does not require specific investigation. For example, a woman in her late 40s with oligomenorrhea and classical menopausal symptoms is almost certainly perimenopausal and no blood tests are needed. Equally, a woman in her mid 50s with at least 12 months amenorrhea has gone through the menopause and no specific tests are required to confirm that. However, in other clinical situations, it can be helpful to confirm the diagnosis or, perhaps more commonly, to refute the diagnosis, for example, in a woman in her mid 40s with vague symptoms who thinks she is going through the menopause. Here normal FSH/LH levels will help to reassure that this is not the cause. It is mandatory however to investigate women suspected of undergoing a premature menopause. The implications of the diagnosis have major long-term consequences in terms of both long-term treatment and also potential fertility. The younger women (under 40) require detailed assessment and specialist assessment.

What Investigations

FSH measurements are the most useful for confirming the diagnosis. A level of >30 IU/L is considered diagnostic of menopause. However, there is significant daily variation of FSH levels throughout the cycle and the results should be interpreted with caution and repeated if necessary. The tests are best done on day 3–5 of the cycle when FSH levels are usually at their lowest. To confirm that a woman with amenorrhea or who has been hysterectomized is menopausal, 2 measurements at least 2 weeks and up to 3 months apart are recommended. FSH levels are no use in predicting when menopause will occur or assessing fertility status. Equally monitoring FSH levels on treatment is of little value. There is no value in using estradiol, progesterone, testosterone, or LH levels in the diagnosis of menopause. Estradiol levels may be useful in monitoring treatment in certain situations.

Thyroid function (T4 and TSH) should be checked if there are any clinical suspicions as the symptoms of hypothyroidism can be confused with menopause or may explain poor response to estrogens. In resistant cases of intractable hot flushes, 24 hour urinary collections of catecholamines (VMA), 5-hydroxyindoleacetic acid, and methylhistamine may be done to exclude rare causes such as pheochromocytoma, carcinoid syndrome, and mastocytosis, respectively.

Further Assessment

The menopause presents an opportunity to screen for significant disease in later years and introduce appropriate preventative measures. There is a wide range of investigations that can be performed:

- Breast screening and mammography
- Endometrial assessment of unscheduled bleeding
- Cardiovascular disease risk assessment
- Skeletal assessment including bone density estimation and fracture risk assessment

While the majority of these are unlikely to be instigated by a urogynecologist, some understanding is helpful. A more detailed description can be found elsewhere [7].

EFFECTS OF THE MENOPAUSE

The menopause can have significant effects throughout the body, which vary chronologically and are summarized in Table 60.2.

Menopausal Symptoms

Vasomotor symptoms, which usually manifest as hot flushes or night sweats, are the commonest symptoms of the menopause. Their exact cause is unknown, but among the many theories, it is hypothesized that a fall in circulating estrogen levels disrupts the control of the body's thermostat, located in the hypothalamus, leading to cutaneous vasodilatation and heat loss [8]. Classically, the hot flush only affects the upper trunk and head and neck. Recent renewed interest in the cause of the hot flush has implicated a possible role for serotonin and its receptors in the central nervous system [9]. Certain triggers can be identified such as stress, spicy foods, alcohol, caffeine, and hot drinks although these are often very individual. Typically, hot flushes start to occur a year or two before the menopause, peaking in frequency and intensity in the first year after menopause and on average lasting for up to 5 years. However, they can continue for 20 or more years and some unfortunate individuals continue to flush all their lives [10].

Table 60.2 Effects of the Menopause in Different Time Frames

Short term
Vasomotor symptoms (e.g., hot flushes, night sweats)
Psychological symptoms (e.g., labile mood, anxiety, tearfulness)
Loss of concentration, poor memory

Joint aches and pains
Dry and itchy skin
Hair changes
Decreased sexual desire
Intermediate
Vaginal dryness, soreness
Dyspareunia
Sensory urgency
Recurrent urinary tract infections
Urogenital prolapse
Long term
Osteoporosis
Cardiovascular disease
Dementia

About 70% of women in the west experience some form of vasomotor symptoms, but their intensity varies enormously. For some women, they are a minor nuisance, but for others, they can be very disabling and can have a major impact on their quality of life. Flushes occurring at night can lead to night sweats, which may disrupt sleep and lead to tiredness, which in turn can affect mood, concentration, and libido.

Psychological Symptoms

Symptoms such as irritability, depressed mood, anxiety, loss of memory and concentration, overwhelming tiredness, and mood swings are common around the menopause, and there is peak prevalence of women seeking help from their GP for this type of problem at this time [11]. However, whether these problems are actually caused by falling estrogen levels or a secondary effect of other menopausal symptoms or due to other coexistent factors is not clear. Several longitudinal studies have not demonstrated any association between depressed mood and the menopause transition [12,13]. Women who report psychological symptoms at the menopause are more likely to have had previous psychological problems, poor health, and premenstrual problems and have current life stresses such as dependent relatives, relationship problems, and negative attitudes to aging and the menopause [14]. The menopause occurs at a time of life when there can be many other stressful events going on, and in many societies, the woman is often the lynchpin that keeps many families together. The additional physical and emotional changes that occur at the menopause can put this balance under pressure and some women will struggle to cope. Whatever the underlying cause, many women do need additional support during this time and some may benefit from specific treatment for their symptoms such as hormone replacement therapy (HRT).

Genitourinary Problems

During the fourth to seventh weeks of fetal development, the urogenital sinus separates from the cloaca and develops into the bladder and proximal urethra in the upper part and the distal urethra and the vestibule of the vagina in the lower part. This shared embryological origin explains why both the genital tract and the lower two-thirds of the urinary tract are rich in estrogen and progesterone receptors and why the loss of estrogen at the menopause can lead to the symptoms and signs of urogenital atrophy. Urogenital atrophy is a common observation in postmenopausal women, which increases with age, but the prevalence of symptomatic atrophy is unclear. In a population-based study of Australian women observed over 7 years, vaginal dryness was a complaint in 3% of premenopausal women, 4% of women in early menopause, but up to 47% of women 3 years or more into their menopause [15].

Vaginal atrophy results in loss of the normal architecture within the vaginal epithelium (Figure 60.3), reducing its secretions and elasticity and making it more prone to trauma, dryness, spontaneous bleeding, and infection. Clinically, this manifests as vaginal dryness, itching, dyspareunia, vaginal pain, discharge, and bleeding. The term genitourinary syndrome of menopause (GSM) is now preferred to vulvo-vaginal atrophy or urogenital atrophy as it provides a more accurate and comprehensive description of this common symptomatic postmenopausal condition [16]. An increased incidence of

STDs is now being reported in postmenopausal women [17]. In part, this may be related to the increasing numbers of postmenopausal women restarting sexual activity but also because a hypoestrogenic vaginal epithelium is more susceptible to acquiring infection [18].

A midlife peak of urinary symptoms around the menopause has also been reported by numerous epidemiological studies [19–21] (Figure 60.4). Women with depressed mood scores are more likely to report symptoms of urinary incontinence [22]. Although loss of estrogen is not the principal cause of most urinary symptoms, there is no doubt that atrophy of the distal urinary tract and in particular the urethra and trigone can lead to troublesome symptoms. Typically, these women describe urinary frequency and dysuria in the absence of proven infection, sometimes referred to as the "urethral syndrome." Thinning of the urethral mucosa and trigone results in a more sensitive and trauma-prone bladder, which in turn leads to sensory urgency and recurrent urinary tract infections, symptoms that respond well to local estrogen administration [23]. Loss of estrogen also plays a role in more widespread pelvic floor dysfunction, leading to weakening of the supporting tissues and ligaments, which may already be damaged by childbirth or other traumas, thus contributing to the increased incidence of prolapse and stress urinary incontinence seen after menopause [24]. Thinning of the urethral mucosa due to atrophy probably contributes to incomplete closure of the urethra, leading to a reduction in urethral closure pressure, which may be a factor in the development of stress incontinence [25].

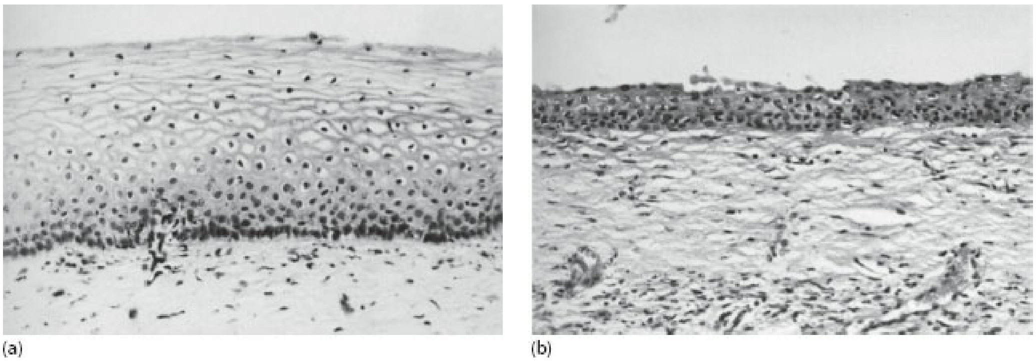

Figure 60.3 Vaginal epithelium in (a) premenopausal woman (left) and (b) postmenopausal woman (right) showing atrophic changes. (From Whitehead MI et al., *Atlas of the Menopause*, Parthenon, Athens, Greece, 1993. With permission.)

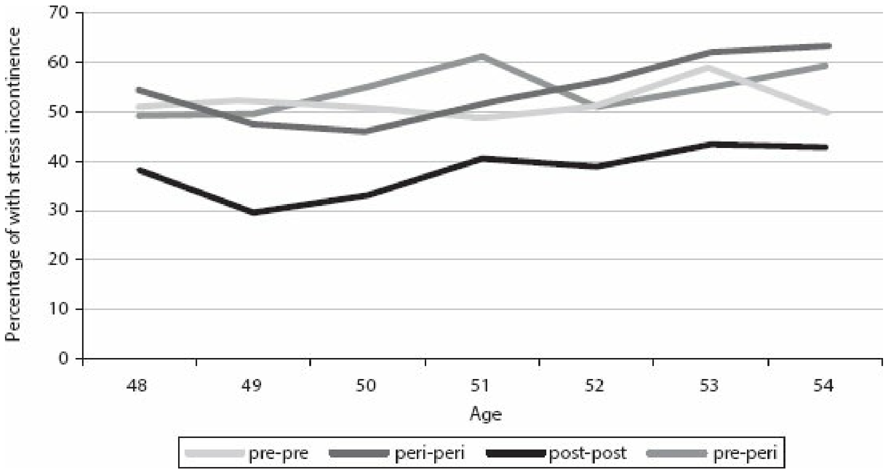

Figure 60.4 Percentage of women in selected menopausal transition categories with stress incontinence by age (n = 843). (From Mishra GD et al., *Br J Urol Int*, 106(8), 1170, 2010. With permission.)

Sexual Dysfunction

Many women complain of loss of sexual desire or libido around the menopause. The term female sexual dysfunction is now in widespread use based on a classification system introduced by the International Consensus Development Conference on Female Sexual Dysfunction [26].

The U.S. National Health and Social Life Survey [27] reported that among 18–59-year olds, sexual dysfunction was more prevalent in women (43%) than men (31%) and that the prevalence of sexual dysfunction rose from 42% to 88% during the menopausal transition. Dennerstein et al. [12] found an increased prevalence of sexual dysfunction but concluded that this was primarily secondary to vaginal atrophy and relationship difficulties. Hormonal changes and in particular loss of estrogen may have a direct effect on sexual desire and function, but the underlying reasons behind sexual dysfunction are often multifactorial. For many women, sexual desire naturally decreases with age and the menopause may coincide with other stressful major life events. In addition, menopausal symptoms and vaginal atrophy may lead to tiredness and discomfort; there may be reduced response to sexual stimuli and more difficulty reaching orgasm. Male partners may also have reduced interest and have difficulty getting or maintaining an erection. This is undoubtedly a complex area but one that does require some understanding particularly in women presenting with other genital tract problems for whom maintaining sexual function is important.

Correction of physical symptoms, often with systemic or vaginal estrogens, may be sufficient in many cases to overcome the problem, but in other women, the causes are more complex and may benefit from psychosexual input. In western society, the menopause is often viewed as a negative event and some women suffer with low self-esteem, which undoubtedly does not help, but in some cultures, the menopause can be associated with an increase in libido as the shackles of monthly bleeding and risk of pregnancy are finally cast off. The role of testosterone and other treatments are discussed later.

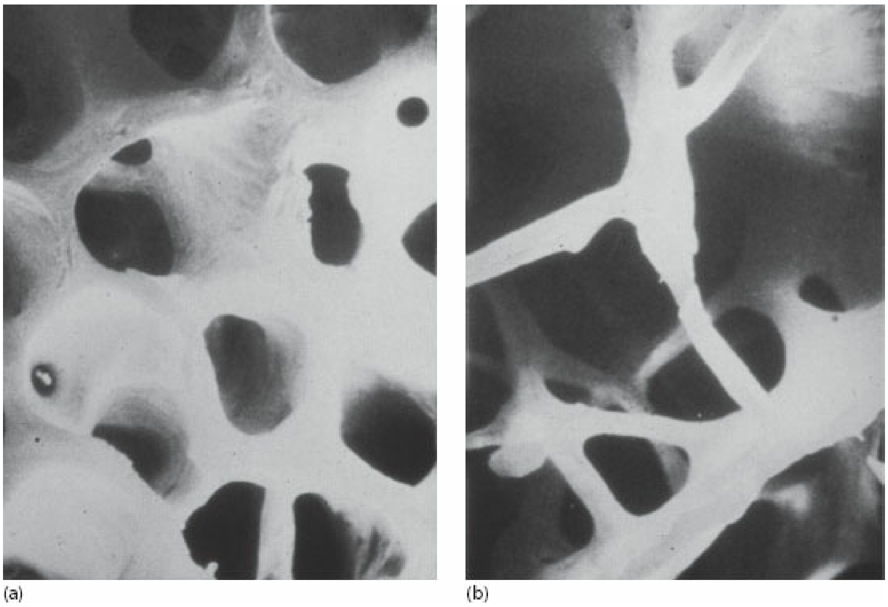

Figure 60.5 Electron micrograph of trabecular bone showing (a) normal structure (left) and (b) osteoporotic bone (right). (From Whitehead MI et al., *Atlas of the Menopause*, Parthenon, Athens, Greece, 1993. With permission.)

LONG-TERM EFFECTS

Estrogen receptors are widespread throughout the body and the fall in circulating estradiol levels leads to a number of changes in a variety of organs and systems that can have notable effects on quality of life and a potentially major impact on long-term morbidity and mortality. These conditions often develop without obvious clinical manifestation in the early postmenopause but pose a significant economic burden for the future particularly with an increasingly aging population. For women who undergo a premature menopause, the prolonged time they spend without estrogen increases the risk of these conditions developing at a younger age.

Osteoporosis

Osteoporosis is defined as “a skeletal disorder characterised by compromised bone strength predisposing to an increased risk of fracture” [28]. Bone strength is principally a reflection of bone quality and bone density (Figure 60.5). The latter is clinically most relevant as it can be readily measured and a woman’s osteoporotic risk assessed using standard WHO criteria (Table 60.3). Osteoporosis is a major health problem for the Western world that will only worsen as the population ages. The commonest sites of osteoporotic fracture are the neck of femur, wrist, and vertebrae, but any long bone is susceptible. Osteoporosis is far more prevalent in women than men, and it is estimated that as many as 50% of women will suffer an osteoporotic fracture in their lifetime [29].

Table 60.3 Definitions of Osteoporosis (World Health Organization)

Description	Definition
Normal	BMD value between −1 SD and +1 SD of young adult mean (T score −1.0 to +1.0)
Osteopenia	BMD value between −1 SD and −2.5 SD of young adult mean (T score −1.0 to −2.5)
Osteoporosis	BMD value equal or below −2.5 SD of young adult mean (T score −2.5 or below)
Established osteoporosis	BMD value equal or below −2.5 SD of young adult mean (T score −2.5 or below) plus one or more fragility fracture

Bone density peaks in the midtwenties as a result of genetic and environmental influences and starts to decline in the mid 40s with an accelerated phase of around 6–10 years after menopause. Thereafter, there is a steady decline with advancing age. The accelerated postmenopausal loss is largely due to the loss of estrogen, which has antiresorptive actions. This results in an accelerated phase of bone resorption and loss of trabecular bone. The rapid fall in bone density immediately after the menopause has triggered a wide range of strategies to prevent osteoporosis over the last 30 years [30]. Estrogen replacement has been proven to both reduce bone loss [31] and reduce the subsequent rate of hip fracture in low-risk populations [32] and is thus an effective preventative treatment in appropriate individuals (see “Benefits of HRT” section at individuals identified as high risk of subsequent fracture rather than treating large sections of the population. Current models, such as the FRAX model [33], screen postmenopausal women for risk factors including age at menopause (premature menopause being particularly high risk). Those deemed as increased risk undergo DEXA bone scanning and those with low bone density offered preventative treatment. There is much debate about when to start preventative treatment as long-term treatments have potential adverse effects and are costly. In the UK, NICE (National Institute of Clinical Excellence) guidance favors a very limited role for preventative treatment in women under 75 except those with previous fracture [34]. This is contrary to previous guidance based on a more clinical approach [35]. Prevention of osteoporosis remains a lifelong strategy even if for some or most of that time no specific treatment is used. A detailed description of all the treatments and their potential role can be found elsewhere [30,31,36].

Coronary Heart Disease (CHD)

While CHD is the single commonest cause of death in women in the United Kingdom, it is relatively uncommon before the menopause. Menopausal status is considered an independent risk factor [37], and after the menopause, the risk increases considerably and there is a large body of evidence suggesting that estrogen has a protective influence against CHD [38]. Early oophorectomy without additional estrogen is associated with a two- to fourfold increased risk of CHD compared to premenopausal women of similar age [39], and large-scale population studies over 20 years suggested that taking estrogens around the time of the menopause leads to a reduction in risk [40]. Estrogens reverse many of the adverse changes in cholesterol and other postmenopausal CHD risk factors [41] and also appear to reduce atherogenesis in animal studies [42]. However, the large Women’s Health Initiative (WHI) randomized trial did not show any convincing evidence that taking estrogen after the menopause has any CHD benefits [43]. The mean age of women in this study was 63 years, but when the data were reanalyzed for those women under the age of 60, no harmful effect was found; indeed there was a suggestion of a beneficial effect [44]. This is more consistent with the previous epidemiological data that estrogens that started around the time of menopause may have a beneficial effect on future CHD risk [45]. A recent 10-year randomized trial of women receiving HRT that started early after menopause observed a significant reduction in mortality, heart failure, and stroke compared to the untreated group

[46].

Dementia

Decline in cognitive function inevitably occurs with age, but once this interferes substantially with social or occupational functioning, it becomes dementia. The incidence of dementia, of which Alzheimer's disease is the commonest form, is increasing and doubles every 5 years after the age of 65 [47]. Alzheimer's disease is more common in women than men, and estrogen receptors are widespread in the central and peripheral nervous systems facilitating autonomic regulation and cognitive function. However, the evidence for a role of estrogen and menopause in the pathophysiology of cognitive decline and dementia is conflicting and may depend on age and timing of intervention. During the menopause in two midlife studies, 36%–62% of women reported memory changes [48,49], but natural menopause does not seem to be associated with objective loss of memory [50]. However, early surgical menopause is associated with an increased risk of dementia in later life, as well as other neurological problems [51]. A meta-analysis of postmenopausal estrogen use around the time of the menopause suggested that it may improve cognitive function and reduce the risk of Alzheimer's disease [52]. Conversely, the WHI memory study reported an increased incidence of dementia with HRT usage; however, this was in a relatively old population (over 65 years), who wouldn't normally expect to be starting estrogens [53]. If estrogens do have any beneficial effect on cognitive function and dementia, they probably need to be started around menopause, but there is insufficient evidence at the moment to suggest this is a benefit of HRT.

MANAGEMENT

The menopause is a natural event, and for many women, there is no need to "manage" it at all, although awareness of the long-term implications such as osteoporosis and cardiovascular disease should be part of good preventative medicine. However for other women, the menopause can be a difficult time and there are a variety of treatment options available. While HRT is an extremely effective option, it is only one of a number of possible approaches. For most women, menopausal symptoms are relatively short lived and will settle within a few years, but for some they will go on much longer and longer-term treatment may be needed. The menopause is a hormonal milestone and provides an opportunity to establish firm strategies for the prevention of the long-term disorders outlined earlier.

Lifestyle

Dealing with the effects of the menopause should incorporate a holistic approach. It is an ideal time to encourage lifestyle changes that can build for a healthy future and help maximize health potential. For many women, the menopause can be a time of uncertainty and may be the first time they've sought professional help for themselves for many years. Smoking is associated with an earlier menopause and an increased risk of cardiovascular disease, lung cancer, and osteoporosis. Smoking cessation leads to a steady reduction in all the increased risks and should be encouraged as part of a health promotion strategy.

Diet

Body weight increases on average 1 kg/year around menopause, although this does not seem to be a direct effect of the menopause itself [54]. In addition, there are metabolic changes and changes in body fat distribution with body fat shifting from the hips and thighs (gynecoid) to a more android distribution (abdomen) [55]. Thus, it is particularly important that women going through menopause eat sensibly and try and avoid excessive weight gain. A recommended diet should be rich in fruit and vegetables, whole grain and high-fiber foods, oily fish twice a week, saturated fat intake less than 10%, cholesterol less than 300 mg/day, alcohol intake no more than 1 unit/day, and sodium to 1 tsp/day [56]. For women with obesity problems, entering the menopause specialist dietary advice may be helpful. HRT is not per se associated with an increase in weight gain [57] although in some women it can increase fluid retention and over time may lead to a reversal of the body fat changes seen at menopause.

Exercise

Regular physical activity has positive effects on a variety of conditions and physical activity can be effectively used to reduce vasomotor symptoms [58] possibly by an effect on endorphins. Regular exercise, even of relatively low intensity, can be beneficial to cardiovascular health [59]. Exercise also has a key role to play in the maintenance of bone health; not only does regular weight-bearing exercise help to conserve bone density in the hip and spine, it also helps to maintain muscle strength, joint flexibility, and overall balance, all factors that will reduce the risk of falls and subsequent fracture [60].

Alternative and Complementary Therapies

A wide variety of nonhormonal prescription drugs, complementary and alternative medicines, are used to improve menopausal symptoms. Some of the licensed preparations such as clonidine, venlafaxine, and gabapentin have short-term randomized trials demonstrating their efficacy [61], but robust evidence for the efficacy and safety of most of the complementary and alternative products or methods is notably lacking [61]. Despite this, the use of such treatments is widespread and increasing [62]. In our own clinic, we identified that up to 40% of women were taking additional over-the-counter supplements for their menopausal symptoms and 10% were taking more than four different products concurrently [63]. These products are currently unregulated in the United Kingdom, and while the majority are likely to be harmless, a number of serious and potentially fatal interactions have been reported between herbal supplements and standard medications [64]. By contrast, the use of phytoestrogens, plant substances with similar activity to estrogen, and black cohosh appear to have some beneficial effects on menopausal symptoms [61]. A meta-analysis of 17 RCTs of soy and red clover isoflavones demonstrated a significant reduction in hot flushes particularly in those with frequent flushes [65]. The effects on other parameters such as bone loss are less clear. Cognitive behavioral therapy (CBT) can also be effective in alleviating low mood or anxiety that arise as a result of the menopause [61].

Hormone Replacement Therapy

HRT is the mainstay of medical treatment available for troublesome menopausal symptoms and simply acts by replacing the hormones that are normally produced by the human ovary at physiological levels. Estrogen is the principal hormone and can be given either alone or in combination with progestogen, which should be given to all nonhysterectomized women. A third hormone, testosterone, can also be given in conjunction with estrogen.

Estrogen

There are a variety of different types of estrogen available, which can be given at varying doses and by different routes [66]. For the vast majority of women, the type and route of administration are not important, and provided an adequate dose of estrogen is given, it is likely to be effective. However, there are some women who do not show an appropriate response and adjustment to a different type of estrogen may be helpful.

The appropriate dose depends on age and severity of symptoms, but as with any treatment, the lowest effective dose should be used. Generally, 1 mg estradiol, 0.625 mg conjugated equine estrogens (CEEs), or 50 mg transdermal estradiol is a reasonable starting dose for an average peri- or early postmenopausal women. The dose may be increased if symptoms are not controlled. Very low or ultralow doses of HRT (0.3 mg CEE or 0.5 mg of estradiol or 14 mcg transdermal estradiol) may also be effective in relieving menopausal symptoms [67,68] and slowing down the rate of bone loss [69].

Different routes of estrogen administration have different pharmacokinetic profiles. Nonoral routes, such as percutaneous and transdermal administration, avoid the first-pass effect with consequent less impact on coagulation and hemostatic mechanisms, making them more suitable for women at increased venous thromboembolism (VTE) [70]. However, oral estrogens, because of their first-pass effect, have potentially greater beneficial effects on lipids and lipoproteins and glucose and insulin metabolism [66,71], so women with hypercholesterolemia or hypertriglyceridemia may benefit more from oral estrogens. For the vast majority of patients, the route of administration is not important provided adequate estrogen levels are achieved. Nonoral routes tend to be more expensive, and for those women who need a progestogen, there can be logistical problems administering the progestogen component simultaneously.

Progestogens

Giving unopposed estrogens to nonhysterectomized women substantially increases their risk of developing endometrial cancer [72]. Progestogens added for at least 10 days per calendar month negate this risk [73]. They can be given either cyclically, mimicking the natural 28-day cycle and resulting in a regular withdrawal bleed, or continuously to prevent any bleeding, so-called “no-bleed” treatment. The latter is usually recommended for women who are clearly postmenopausal, while the former is usually prescribed for women who are perimenopausal. Long-cycle HRT can also be used where progestogen is added for 2 weeks every 3 months. While this has potential advantages in limiting withdrawal bleeds to 4/year, it carries an increased risk of breakthrough bleeding and potential endometrial abnormalities if continued long term [74].

There are several different types of progestogen used in HRT (Table 60.4). Side effects are common, particularly in the first few months, and these may vary depending on the type and dose of progestogen used. Switching from one type of progestogen to another or changing the route of administration can alleviate side effects in many cases. The advent of the levonorgestrel intrauterine system has allowed many women who could not tolerate any of the available progestogen combinations to continue HRT safely. However, all progestogens are not necessarily equal [66] particularly in their possible cardiovascular [75] and breast [76] effects.

Table 60.4 Different Progestogens Used in Hormone Replacement Therapy

Norethisterone (transdermal)
Levonorgestrel (transdermal, intrauterine)
Dydrogesterone
Medroxyprogesterone acetate
Drospirenone
Micronized progesterone (rectally)
Cyproterone acetate (not available in the United Kingdom)

Note: All are available orally. Additional routes are listed.

Testosterone

Fifty percent of testosterone production in women is from the ovaries (the other 50% is from peripheral fat stores and the adrenals). Testosterone production is not generally affected by natural menopause although a decline in sex hormone binding globulin (SHBG) may lead to a small rise in circulating free testosterone. However, women who undergo a surgery- or chemoradiation-induced menopause may become relatively testosterone deficient. Symptoms can be hard to determine specifically but classically are loss of libido, decreased sexual activity, fatigue, and reduced feelings of physical well-being [77]. There are a number of potential treatment options that are discussed later.

BENEFITS AND RISKS OF HRT

Prescribing any medication or intervention requires careful weighing up of the potential benefits and possible harm for that individual and should be done in careful informed discussion with the woman. The role of HRT has been the subject of considerable scientific and public debate in recent years, so it is important that up-to-date evidence and recommendations are used to inform any discussion [61,78–80] (Table 60.5).

Table 60.5 Benefits and Risks of Hormone Replacement Therapy Based on Grade A or B Evidence

	Benefits	**Risks**
Grade A	Vasomotor symptoms	VTE
	Urogenital symptoms	Endometrial cancer
	Osteoporosis	Gall bladder disease
	Colon cancer	
Grade B	Quality of life	Breast cancer
	Osteoarthritis	Stroke

	Cardiovascular disease	Ovarian cancer
	Sexual function

Benefits of HRT

The majority of women start HRT for the relief of their menopausal symptoms, and there is abundant evidence that estrogen is effective in treating hot flushes [81], with improvement usually noted within 4–6 weeks [61]. Comparative studies indicate that HRT is far more effective than nonhormonal preparations, such as clonidine, selective serotonin reuptake inhibitors, herbal preparations, and phytoestrogens [82,83].

The symptoms of vaginal and urogenital atrophy discussed earlier respond well to systemic or vaginal estrogens [23,61,84]. Systemic HRT offers no benefits over topical therapy for the treatment of genitourinary atrophy; indeed sensory urgency seems to respond better to topical estrogen than systemic estrogen [85]. Topical vaginal estrogens also reduce the frequency of recurrent urinary tract infections, have minimal systemic absorption, and are not associated with the risks associated with HRT (discussed in the following texts). Thus, they are the preferred treatment for genitourinary atrophy and should be continued at a low maintenance dose; otherwise, the symptoms tend to recur.

HRT is effective in the prevention of postmenopausal bone loss and osteoporotic fractures at the spine and hip [77], even in a low-risk population [32]. Thus, women taking HRT for symptom relief will derive benefit as far as their bones are concerned. What has been more debatable is whether or not HRT should be prescribed for osteoporosis prevention alone. The regulatory authorities have advised that HRT should not be used as a first-line treatment for osteoporosis prevention in postmenopausal women as the potential risks outweigh the benefits [86]. However, the long-term efficacy and safety of alternatives for osteoporosis prevention, such as the bisphosphonates, have not been established in younger (<60 years) postmenopausal women, and there are increasing concerns about the long-term safety of these preparations [87–89]. Thus, in this age group, HRT remains a suitable preventive treatment [79,90,91].

For women with premature ovarian failure under the age of 50, all professional bodies including the regulatory authorities agree that HRT is the most appropriate treatment for osteoporosis prevention [61,78–80,86,91].

Risks of HRT

Ever since the introduction of HRT, there has been controversy that the prolongation of exposure to natural hormones may have an adverse effect on the breast and other estrogen-sensitive tissues. Yet despite widespread use for over four decades and numerous studies, there remains uncertainty and controversy about exactly what the risks are and how relevant they are to the majority of healthy postmenopausal women.

Breast Cancer

A large body of epidemiological studies have suggested that less than 5 years of HRT use in the early postmenopause does not increase breast cancer risk [92]. Thereafter, there does appear to be a small increase in risk, dependent on years of exposure. The magnitude of risk appears to be similar to that associated with late natural menopause (2.3% compared with 2.8% per year, respectively). A meta-analysis of all observational data prior to 1997 estimated that current use of any HRT for more than 5 years, when started over the age of 50, increased breast cancer risk by 1.35 (95% confidence interval 1.20–1.49) [92]. In absolute numbers, this equates to 4–5 extra breast cancer cases/1000 women who use HRT from the age of 50 for 5 years. Women who start HRT early for premature menopause do not show this effect, suggesting that it may be the lifetime sex hormone exposure that is relevant. The WHI study [43], which is the largest randomized trial on HRT, reported a broadly similar risk to that seen in the epidemiological studies for combined estrogen and progestogen treatment but also found no increase in risk over 7 years with estrogen-only treatment [93]. There are conflicting reports about what happens to breast cancer risk after stopping HRT. A recent 3-year follow-up of women who were in the WHI trial claimed that the risk of breast cancer remains elevated for 3 years after treatment was stopped [94]. However, these findings are at odds with other recent publications, which imply the risk of breast cancer falls quickly after cessation of HRT [61,95,96].

In summary, otherwise healthy postmenopausal women in their late 40s and 50s wishing to take HRT should be reassured that the overall risk of developing breast cancer in the first few years as a result of their HRT is small [61] (Table 60.6). If they take estrogen alone, that risk is even lower [92,96]. Overall, other personal risk factors such as family history, BMI, and alcohol intake are likely to be more important predictive factors [98].

Endometrial Cancer

Unopposed estrogen replacement therapy increases endometrial cancer risk, which is reduced by the addition of progestogens [72,73]. When continued for more than 5 years, cyclical progestogen addition does not completely eradicate this excess risk, while continuous progestogen addition does [72]. Thus, once a woman is clearly postmenopausal, she should be switched to a continuous combined (no-bleed) regimen. Any abnormal bleeding on HRT should be investigated, although the likelihood of underlying malignancy is much lower than with postmenopausal bleeding (1% vs. 6%) [99].

Ovarian Cancer

Most of the limited data relate to estrogen alone and suggest a small increase in risk in epithelial tumors with very long-term (>10 years) treatment [100]. This increase does not seem apparent with combined therapy [101,102]. There is currently insufficient evidence to recommend any alterations in HRT-prescribing practice [79].

Venous Thromboembolism

HRT increases the risk of VTE twofold, with the highest risk occurring in the first year of use [103]. The background risk of VTE in women over 50 years not taking HRT is small (1.7/1000) [104], so the overall impact of this increase is low. However, the background risk is significantly increased in women who smoke, are obese, have an underlying thrombophilia such as factor V Leiden, or have previously suffered a VTE [103]. Transdermal HRT has less impact on hemostatic mechanisms and appears to be associated with a lower risk of VTE [70,103,105], even in women with a thrombophilia, and thus may be the treatment of choice in this group.

Coronary Heart Disease

Large-scale epidemiological studies have consistently shown that estrogens appear to have a protective effect on CHD [40], whereas some randomized trials have suggested a possible adverse effect [43]. Subsequent detailed analysis of these and other data suggest that timing of the introduction of estrogen may be critical [45,106,107]. For women starting HRT shortly after menopause, there may well be a protective effect on CHD, and this particularly appears to be the case for women undergoing premature menopause. However, in women many years past the menopause, starting HRT may have a detrimental effect, i.e., early benefit and late harm. There is no indication to use HRT for cardiovascular disease protection [79].

Stroke

Small increases in the risk of stroke with both estrogen only and combined estrogen and progestogen were reported in the WHI study [43], although there was a significant age effect, with a relatively high risk in older women and no reported increase in the 50–59 age group. In general, the data suggest a trend toward a small increase incidence of stroke with HRT although transdermal and ultralow-dose oral therapy may have a lower risk [61,78,108,109]. HRT should not generally be initiated for women over the age of 60 or those who have strong risk factors for stroke or cardiovascular disease risk without carefully weighing up the potential risks against any potential benefits.

Table 60.6 Absolute rates of Cardiovascular Disease, Stroke and Breast Cancer for Different Types of HRT Compared with Placebo (or no HRT) in Randomized Trials

	Baseline	**Estrogen**	**Estrogen + progestogen**	**Any HRT**[a]
Cardiovascular Disease	26.3	6 fewer (−10 to +1)	5 more (−3 to +18)	6 fewer (−11 to +5)

Stroke	11.3	0 (−5 to +10)	6 more (−2 to +21)	3 fewer (−7 to +8)
Breast Cancer	22.48	4 fewer (−11 to +8)	5 more (−4 to +30)	9 fewer (−16 to +7)

Note:Difference in incidence per 1000 menopausal women (aged 50–59) over 7.5 years (95% confidence interval). Baseline population refers to risk in the UK over 7.5 years.

[a] Studies did not specify type of HRT.

Practical Considerations for Prescribing HRT

HRT is only one option for dealing with menopausal symptoms and other options should be considered [61,82,83]. Yet despite the recent controversies, HRT remains a clinically effective and cost-effective strategy for women with menopausal symptoms [110]. For the majority of healthy symptomatic menopausal women, the potential benefits will outweigh any small risks [61,78–80]. However, like all treatments, the risks and benefits should be weighed upon individually with the patient before starting treatment.

Selecting which HRT regimen is a matter for the individual prescriber. If there are specific special circumstances, then a particular type or route of administration may be most appropriate. Follow-up should be arranged after a few months to check the treatment’s effectiveness and side effects. It is common for women to have some problems in the first few months, and if these do not settle down, a change of preparation may be advisable. Treatment should be started at the lowest appropriate dose and can be increased if there is no symptomatic improvement after a few months.

The duration of HRT use depends on the individual circumstances and indication for taking it. The “average” menopausal woman in her early 50s will probably only need it for 1–2 years, but there is no reason why she shouldn’t take it for longer if indicated. The Medicines and Healthcare Products Regulatory Agency (MHRA) recommend taking “the minimum effective dose” of HRT for the “shortest duration” without defining any specific length of time [86]. Based on other recommendations, this has generally been interpreted as about 5 years, although in reality most women don’t take it that long. However, treatment can be continued for longer in women with persistent troublesome symptoms that adversely affect their quality of life. For women with POI, the risk/benefit balance is strongly in favor of them taking HRT at least up until the age of 50 as a true physiological replacement [61,86,111].

For all women, their individual risk of VTE, stroke, and breast cancer should be appraised regularly and balanced against the benefits she is gaining from the treatment. For the majority of women, the overall increase in any risk will be very small and there are some women who opt to continue taking HRT for its benefits well into their 60s.

Stopping HRT should be done gradually reducing the dose to avoid rebound symptoms. At the same time, positive lifestyle factors should be emphasized, such as diet and regular exercise. Vaginal estrogens can be added in if troublesome genitourinary symptoms persist. As they are not absorbed systemically to any great extent, they can be continued after HRT has been stopped without significant risk [112].

Reduced sexual desire is a common complaint around the menopause, which can lead to distress and have a negative impact on psychological well-being and relationships [113]. This is a complex area and there are often multiple factors that play a part [114]. Menopausal symptoms and urogenital atrophy should be treated with systemic or local estrogens, and psychosexual counseling should be considered if appropriate. Testosterone supplementation appears to be effective in postmenopausal women when given orally or transdermally as a patch or gel in women with low sexual desire [115]. This is seen in both surgical and naturally occurring menopause [116,117] with or without concomitant estrogen treatment [118]. Subdermal testosterone implants, which have been used for many years in some countries, are no longer readily available. However, a transdermal testosterone cream, which is now available in Australia, may be a suitable alternative [119]. Tibolone, which is a synthetic steroid with estrogenic, progestogenic, and androgenic activity, has a licensed indication for women with loss of libido [120].

Contraception

Contraception should be continued until 2 years after the last period in women under 50 and 1 year in women over 50. A full review of contraceptive choices for perimenopausal women can be found elsewhere [121].

SUMMARY

The menopause is a time of significant physiological change signifying the end of the reproductive phase of life. While this can be a positive development for many women, for others, the menopause can be a difficult time with distressing symptoms that impact on their quality of life, their employment, and their relationships. The potential impact on long-term health should also be considered, and the menopause provides a good opportunity to improve lifestyle risk factors and put long-term prevention strategies in place. Women with premature ovarian failure have particular needs and will often benefit from specialist support. A wide range of potential treatments is available for helping women through the menopause and beyond. HRT is only one option but is effective and has a large body of evidence supporting its use. For the vast majority of healthy symptomatic menopausal women, the benefit/risk balance is in favor of using it for a limited period. No two women's experience of the menopause is exactly the same and any advice or treatment should therefore be tailored to the needs of the individual woman.

61 Sports and Fitness Activities

Kari Bø

Urinary incontinence is often regarded as a problem affecting older, postmenopausal, multiparous women [1]. However, several epidemiological studies have demonstrated that the symptom of stress urinary incontinence (SUI) is also common in populations of nulliparous young females [1–10]. Prevalence data vary between 12% and 52% and may be explained by differences in definitions, study design, and populations. Typically, for prevalence studies the percentage tends to drop when the former International Continence Society (ICS) definition of symptoms being socially and hygienically problematic is used [6,11].

The most common type of urinary incontinence in women is SUI [12], defined as involuntary leakage on physical exertion, sneezing, or coughing [13]. Cross-sectional studies in the general female population reporting that physically active women have less incontinence compared to their sedentary counterparts are difficult to interpret as this association may be because women with incontinence have stopped exercising due to the condition [10,14–20]. Hence, the unanswered question is: Does physical activity cause continence, or are women able/willing to participate in physical activities because they are continent?

ASSESSMENT OF INCONTINENCE DURING PHYSICAL ACTIVITY

Usually, the diagnosis of urodynamic SUI is made during assessment in a half-sitting, lithotomy position. The validity of this evaluation can be questioned as most women only leak in a standing position. Some pad tests involve physical activities such as stair climbing and jumping [21]. Henalla et al. [22] and Hagen et al. [23] designed tests based on physical activities. The latter test involved running, jumping jacks, standing up and lying down, and abdominal curls. These were found to be nine times as provocative as the ICS test involving physical activity. The authors concluded that assessment of the degree of SUI has to be physically provocative to detect SUI. Nygaard et al. reported that 7% of women admitted to urine loss only during sports, and that 40% and 17% first noted urinary incontinence during sports while in high school or junior high school, respectively [1].

Methodological problems in study design have meant that there is a lack of studies describing bladder and urethral function during physical activity. James [24] argued that assessment of SUI should be performed in standing and working positions and during physical activity. He used ambulatory bladder pressure measurements to demonstrate peaks of bladder pressure rise during running and jumping, which occurred when the feet touched the ground. Although pressure rise was higher during coughing, some women were only leaking during exercise.

Kulseng-Hanssen and Klevmark [25] improved the methodology by placing bladder and urethral transducer catheters in a silicon cuff and sutured it to the external urethral opening to keep it stable during activity. In 16 of the patients, 115 leakage episodes were seen in 45 minutes. In 92 of these episodes, the maximum urethral pressure decrease was larger than the detrusor pressure increase. However, some patients complained of urinary leakage during strenuous exercise (running and jumping for longer periods of time), although leakage was undetected even in this test. Similar results were seen in the study of Bø et al. [26], where the test did not detect leakage in four subjects with convincing history of urinary leakage. As SUI may occur due to fatigue of the striated urethral wall and pelvic floor muscles (PFMs), some women may need even more vigorous and continuous activities to provoke the leakage they experience outside the laboratory.

Comparing change in foot arch flexibility in 47 continent and incontinent varsity athletes, Nygaard et al. [27] demonstrated a significant decreased foot flexibility in incontinent women. They suggested that the way in which impact forces are absorbed may be one etiological factor for stress incontinence and that more research is required to understand how impact forces are transmitted to the pelvic floor. The high prevalence of urine loss in gymnasts may be explained by the extremely high impact during landing and takeoff and the transmission of this pressure to the pelvic floor. However, despite this high impact, many gymnasts do not leak, and this group is therefore interesting and important to study.

PREVALENCE OF URINARY INCONTINENCE AMONG PARTICIPANTS IN SPORTS AND FITNESS ACTIVITIES

SUI implies that urine loss occurs during an increase in abdominal pressure. Therefore, one may expect that women with this condition are likely to experience urine loss during participation in most forms of physical activity. Sedentary women are less exposed to physical exertions and this may avoid urinary leakage, despite the underlying condition potentially being present.

Studies have demonstrated that SUI is common among physical education/sport students, women who exercise for fitness, and female elite athletes [28]. Bø et al. [7] demonstrated (in a study with 84% response rate) that 26% of young physical education/sport students reported having urinary leakage during different forms of physical activity. This study also showed a difference between a group exercising three times a week in addition to daytime physical activities at the university and a group of sedentary nutrition students. The respective prevalences were 31% and 10% ($p = 0.02$).

A subsequent study of first-year female students ($n = 37$) with a mean age of 20.2 years demonstrated a prevalence of 38% of SUI symptoms. Eight of 13 women (61.5%) considered the leakage a social or hygienic problem [26], giving a prevalence using the former ICS definition of 21.6% for this population of physically fit, young, exercising nulliparous women. In this latter study, ambulatory urodynamic test was used to verify urodynamic SUI. Seven women with symptoms were evaluated by urodynamics, and in six of seven, urethral sphincter incompetence was confirmed. Mean leakage measured by pad test with standardized bladder volume was 12 g (range 0–46 g).

Nygaard et al. [9] studied incontinence and exercise in a group of 326 women presenting to private gynecology offices (response rate 50%). Eighty-nine percent were exercising at least once per week, with an average of three times per week for 30–60 minutes per session. Forty-seven percent reported some degree of urinary incontinence.

Fozzatti et al. [29] found that 24.6% of nulliparous women attending gyms compared to 14.3% in a group not attending gyms or doing high-impact activities (except running) reported UI, $p = 0.006$. This supports the results from a study on group fitness instructors, showing a prevalence of 26%, with the same prevalence in those teaching yoga and Pilates [30].

There is a lack of information about incontinence in female elite athletes. In a systematic review, Bø [28] found a variation in prevalence between sports from 0% in golfers [1] up to 80% in high-impact sports [31]. Nygaard et al. [1] surveyed all 156 women participating in varsity athletics at a large state university. The response rate was 92%. Mean age was 19.9 ± 3.3 years and they were all nulliparous. The women were asked whether they had ever experienced urinary leakage during participation in sports, during coughing, during sneezing, during heavy lifting, when walking to the bathroom, during sleeping, and upon hearing the sound of running water. They rated frequency of leakage in a five-point scale. Twenty-eight percent reported urine loss while participating in their sports. There was a tendency in two-thirds of these women to be incontinent frequently rather than rarely. The proportion in different sports was as follows: gymnastics, 67%; basketball, 66%; tennis, 50%; field hockey, 42%; track, 29%; swimming, 10%; volleyball, 9%; softball, 6%; and golf, 0%. Sixteen percent were incontinent during practice sessions and 14% during competition [1]. Forty-two percent reported urine loss during at least one of the activities of daily life and 18% more often than rarely. Twenty-one percent reported urine loss only during daily life and not during sports, and 7% noted incontinence only during sports. Bø and Sundgot-Borgen [32] compared prevalence of symptoms of urinary incontinence in Norwegian elite athletes and age-matched controls and found a prevalence of 41% and 39% of SUI and 16% and 19% of urge incontinence in athletes and controls, respectively.

In order to find out whether high-impact activity contributes to later urinary incontinence, Nygaard [33] compared former female Olympians who had competed in swimming (low impact) and gymnastics or track and field (high impact). One hundred and four women participated (response rate 51%). When doing their sport as Olympians, high-impact athletes have higher prevalence (36%) compared to low-impact athletes (4.5%). However, when studied more than 20 years after cessation of the sport, there was no significant difference in prevalence of incontinence between the groups. It was concluded that participation in regular, strenuous, high-impact activity when younger did not predispose to significant urinary leakage later in life. Bø and Sundgot-Borgen [34] studied former female elite athletes 15 years later and found that they were not more likely to experience urinary incontinence later in life than controls. Former athletes from high-impact sports (running and jumping) were not more likely to report urinary incontinence. Having experienced urinary incontinence during sports was, however, strongly associated with later incontinence.

CONSEQUENCES OF SUI DURING PHYSICAL ACTIVITY

Urinary incontinence may lead to withdrawal from social activities and reduction of well-being [35]. Norton et al. [36] reported that urinary leakage frequently interfered with daily life in more than 50% of their study group. Additionally, Fall et al. [37] reported that 42% of the women with incontinence had problems during sports and physical activities.

Bø et al. [38] showed that two-thirds of sedentary women with urodynamic SUI reported urinary leakage to be the cause of inactivity. Twenty-seven out of 52 women had tried to participate in specific sports and fitness activities but had withdrawn from one or more activities because of leakage. Nineteen of the 27 women had withdrawn from aerobic and dance activities, despite these being among the most popular fitness activities for women. They all reported that the major leakage occurred during high-impact activities during the aerobics session, especially when performing “jumping jacks” (jumping with legs in subsequent abduction and adduction), which is one of the most commonly used high-impact exercises in aerobic dance and general fitness programs.

This corresponds with the results of Nygaard et al. [9], where women most frequently reported leakage with running and high-impact aerobics. Thirty percent of the exercisers noted incontinence during at least one type of exercise. Twenty percent of these women stopped doing the activity solely because of incontinence, 18% changed the way they performed an exercise, and 55% wore a pad during exercise. Frequency, time spent per session, and duration of a particular exercise had no significant impact on the prevalence [9].

Brown and Miller [10] concluded that urinary incontinence was an important barrier to women’s participation in physical activities. Regular physical activity is an important factor for women’s health at all ages. Moderate physical activity can be one important factor in prevention of coronary heart disease, high blood pressure, osteoporosis, musculoskeletal diseases, obesity, breast and colon cancer, anxiety, and depression [39]. If one consequence of incontinence is withdrawal from physical activity, the impact on women’s health is potentially huge.

CAN PHYSICAL ACTIVITY CAUSE URINARY INCONTINENCE?

Several risk factors have been suggested for the development of female urinary incontinence; hereditary weak connective tissue, weak or nonfunctional PFMs, hormonal factors, dyssynergia between detrusor and urethral smooth and striated muscle activity, pregnancy, vaginal delivery, heavy physical exertion, inactivity, obesity, cigarette smoking, menopause, and old age are suggested risk factors [12,40]. To date, there is little evidence supporting a strong causal effect for many of these factors. The reality is that urinary incontinence has a multifactorial etiology in women including failure of one or more factors to compensate for another weak factor. The speed and strength of the PFM contraction may be one such important factor [41,42].

PELVIC FLOOR AND FEMALE ATHLETES

Optimal PFM function implies a localization of the pelvic floor in an adequate anatomical position, with sufficient cross-sectional area to give structural support for the vagina, bladder, and the urethra in order to prevent descent during increase in the abdominal pressure [43]. The muscles have to be in a neurological state of “readiness for action” allowing an appropriate quick and strong response or be a part of a feed-forward loop, contracting automatically simultaneously or before the intra-abdominal pressure increase.

Typically, there are two hypotheses about female athletes and PFM strength, and the hypotheses are going in opposite directions [28]. The first hypothesis is that general physical activity may lead to reflexive strengthening of the pelvic floor, thus making the PFMs in female athletes stronger. To date, no research has verified this hypothesis. The fact that so many female athletes report SUI [28] actually contradicts this view.

The second hypothesis is that heavy exercise, e.g., marathon running with repetitive bouncing toward the pelvic floor or weight lifting, may overload the pelvic floor and weaken the muscles over time. Nichols and Randall [44] proposed that women exposed to chronic straining may have an increased prevalence of genital prolapse because of connective tissue damage due to persistent intra-abdominal pressure increase. Nichols and Milley [45] suggested that the cardinal and uterosacral ligaments, PFMs, and the connective tissue of the perineum may be damaged chronically because of repeatedly increased abdominal pressure due to, e.g., manual work and chronic cough. According to this theory, strenuous exercise raising the abdominal pressure may contribute to development of SUI in women with a predisposition to incontinence.

Davis and Goodman [46] studied 512 of 2651 female soldiers who entered the airborne infantry and found that nine developed urinary incontinence during the training period. Urodynamic investigation demonstrated “detrusor instability” in three and urodynamic SUI in six of the women. All six with SUI demonstrated a definite cystourethrocele, a hypermobile vesical neck with loss of the posterior urethrovesical angle, and visible urine loss with Valsalva after the training period. Four of the women reported feeling a tearing pain in their lower quadrant on impact during a parachute jump, and one subject related a similar event during heavy lifting and doing sit-ups. From the data available today, it is not possible to conclude whether moderate- to high-impact activities can cause connective tissue or PFM damage. It is likely that there is a self-selection of continent women who undertake high-impact sports and fitness activities.

Another contributing factor for SUI in female elite athletes may be hypothalamic amenorrhea due to either intensive exercise, eating disorders, or a combination of both with resultant low estrogen levels [1]. However, the association between low estrogen levels and prevalence of SUI is not clear [47]. Most women in the studies of Bø et al. and Nygaard et al. reporting and demonstrating SUI had regular menstrual cycles [1,26]. However, in the study by Bø and Sundgot-Borgen [32], a higher prevalence of SUI was found in those with eating disorders. Eating disorders may be associated with low estrogen levels.

Nygaard et al. [1] proposed that, e.g., gymnasts may have selected their sport because of hypermobility and that changes in collagen concentration may be one factor in the higher prevalence of incontinence in gymnasts. However, although some studies have shown reduction in collagen tissue in women with incontinence compared to continent women [48], the link between collagen, hypermobility, and SUI is not clear. There are no studies comparing the collagen structure in gymnasts and athletes with or without SUI with that of matched controls.

There are few studies measuring PFM strength in exercisers compared to sedentary controls. Bø et al. [26] did not find any significant difference between incontinent female sport students and a comparable continent group. However, the sample was small, and other studies have demonstrated significantly stronger PFMs in continent than incontinent women [41,49,50]. Borin et al. [51] compared PFM strength in 10 handball, 10 volleyball, and 10 basketball players and a nonexercising control group and found weaker muscles in the volleyball and basketball players compared with controls. They also found that lower strength correlates with increased symptoms of urinary incontinence. There is an urgent need for further studies on this topic.

PROTECTION DURING EXERCISE TO PREVENT LEAKAGE

Because of the health benefits of regular moderate exercise, it is important to emphasize that women should be encouraged to continue exercising despite their urinary leakage. However, they can be advised about choosing low-impact activities, e.g., walking, Nordic walking, dancing, low-impact aerobics, step training, bicycling, swimming, and cross-country skiing.

If an incontinent woman wants to participate in high-impact aerobics, she may use low-impact alternatives, meaning walking while the others are running, doing “step touch” while others are doing jumping jacks, etc. In addition, if she leaks or feels downward pressure during sit-ups, she should be advised to make an attempt to contract the PFMs before doing abdominal curls/sit-ups. It is important to notice that several studies have found that coughing and Valsalva (as in defecation) increases intra-abdominal pressure to a significantly higher degree than different daily movements and exercises [52,53]. Many exercises including abdominal exercise did not increase the intra-abdominal pressure more than rising up from a chair [53]. Hence, the fear that common exercises may hurt the pelvic floor may be exaggerated.

During exercise, the woman should be encouraged to use specially designed protection. Fortunately, some of the best protecting pads are now manufactured in small sizes, making active women more comfortable when wearing them while exercising. In addition, women may use urethral or vaginal devices to prevent leakage during physical activity [54,55]. In a study of Glavind [56], six women with stress incontinence demonstrated total dryness when using a vaginal device during 30 minutes of aerobic exercise.

TREATMENT

No studies have been found evaluating any treatment methods for urinary incontinence in a defined subgroup of female athletes or exercisers. Generally, the least invasive treatment should be tried first [57], with pelvic floor muscle training (PFMT) being the method recommended as first-line treatment [57]. Female elite athletes are mostly young and nulliparous, and surgery is therefore not recommended.

Several randomized controlled trials have demonstrated a positive effect of PFMT on SUI in the general population [57]. Bø et al. [38] demonstrated that after specific strength training of the PFMs, 17 of 23 women had improved during jumping and running and 15 during lifting. In addition, significant improvement was obtained while dancing, while hiking, during general group exercise, and in an overall score on ability to participate in different activities [38]. Measured with a pad test with standardized bladder volume comprising running, jumping jacks, and sit-ups, there was a significant reduction in urine loss from a mean of 27 g (95% CI, 8.8–45.1; range 0–168) to 7.1 g (95% CI, 0.8–13.4; range 0–58.3), $p < 0.01$ [58].

Two small case series on elite athletes and sport students have been published [59,60]. Rivalta et al. [59] reported total relief of reported symptoms and no leakage on pad testing after 3 months of a combination of electrical stimulation, PFMT with biofeedback, and vaginal cones. Da Roza et al. [60] reported that seven nulliparous sport students significantly improved PFM strength and reduced International Consultation on Incontinence Questionnaire (ICIQ) score and frequency and amount of leakage after 8 weeks of training. Elite athletes and women engaging in fitness activities are used to conducting regular training and are motivated for exercise. One would therefore expect that the effect of supervised PFMT would be equally effective or even more effective in these specific groups of women.

Supervised PFMT has proved to be effective in the general female population; it is a functional and physiological noninvasive treatment with no known side effects that can be very cost-effective compared to other treatment modalities. In addition, the woman herself is given the opportunity to take control over her health. She learns body awareness, and if successful, the training may enhance self-esteem and coping strategies. There is, however, a need for randomized controlled trials to discuss whether PFMT can reduce urinary leakage in subgroups of exercising women.

CONCLUSIONS

SUI is prevalent in exercising women at all levels. This may well be because the activity “unmasks” a predisposition to leak as currently it is not possible to be certain whether strenuous physical activity may cause SUI or pelvic organ prolapse. Current understanding certainly suggests that more vigorous exercise is associated with higher rates of leakage and that women with problems restrict their physical activities. More research is needed to understand how impact from different exercises may affect pelvic organs, connective tissue, and PFMs. The effect of PFMT on elite athletes and women participating in vigorous fitness activities has not yet been evaluated in randomized controlled trials. However, based on the present knowledge on effect of PFMT, it has been suggested as the first choice of treatment.

Anal Incontinence

Tony Mak and Simon Radley

INTRODUCTION

Anal incontinence is the involuntary loss of solid or liquid stool per rectum. It is personally and socially incapacitating and only a half of sufferers will volunteer their symptoms spontaneously if not asked directly [1]. Although it affects men and women of all ages, incontinence is eight times more common in women than in men at the age of 45, implicating obstetric factors in the etiology. A study from Birmingham found that 4% of women develop fecal incontinence following childbirth [2]. The focus of this chapter is on obstetric injuries, which are the underlying cause of anal incontinence in most women, but other causes must be considered (Table 62.1). The principles of management are broadly similar whatever the etiology. Vaginal delivery is the most important etiological factor in postobstetric anal incontinence.

Two principal mechanisms are responsible for the development of fecal incontinence following vaginal delivery:

- Direct injury to the sphincter muscle itself
- Damage to the nerves supplying the pelvic floor or anal sphincter

Less frequently, new symptomatic anal incontinence may occur in women following cesarean delivery.

PATHOGENESIS

Sphincter Injury

Direct damage to the sphincter muscles is responsible for anal incontinence in most of the women who present early after childbirth. Sphincter injuries are more common in primiparous women; new sphincter injuries are less common with subsequent deliveries [3]. Up to 35% of primiparas have been reported to have sphincter injury; however, some remain asymptomatic [4]. Other risk factors or associations for sphincter injury include large babies, forceps delivery, a prolonged second stage of labor, and occipitoposterior presentation [5]. Some authors have raised doubts on posterolateral episiotomy and claims that it does not necessarily protect against sphincter injury [6].

It has become clear that following vaginal delivery anal sphincter injuries may be unrecognized or misclassified as a less severe injury. When perineal examination is undertaken by a trained clinician immediately following delivery, the incidence of detected sphincter injury may be significantly increased [7]. Some sphincter defects may be truly occult, occurring with minimal or no perineal injury, where the mechanism is likely to be tissue shearing during delivery. However, there is a notable variation in the incidence of recognized third-degree tears between centers publishing their data [8], and the observation that women with second-degree tears are the group most likely to develop anal incontinence postpartum [9] further suggests that a proportion of anal sphincter injury remains undetected following delivery. Even when sphincter damage is recognized and repaired at the time of delivery, up to 85% of women still have identifiable sphincter defects and around 50% of women have some symptoms of anal incontinence [5].

The development of incontinence later in life is more likely to be multifactorial in origin, resulting from a combination of one or more factors including sphincter damage, progressive neuropathy, muscle atrophy, hormonal changes [10], and alteration in bowel function [11].

Neurological Damage

Prolonged pudendal nerve motor terminal latencies (PNMTL) are a marker of nerve injury and have been demonstrated in a third of primigravidae following vaginal delivery [12]. These usually revert back to normal, but up to a third remain prolonged at 6 months. The presence of a prolonged PNMTL is not necessarily associated with incontinence. After emergency cesarean section late in labor, pudendal nerve latencies may be increased, implicating damage to the nerves supplying the pelvic floor or sphincter [13]. In some women, electromyographic studies revealed increased fiber density in the external sphincter consistent with damage to sphincter innervation. Pudendal nerve damage and increased fiber density were seen more frequently in multiparae, suggesting that nerve damage may be cumulative with subsequent deliveries. The development of neurogenic incontinence is likely to be a progressive process, rather than an acute event at the time of delivery, and therefore may be exacerbated by subsequent deliveries or prolonged straining.

PATIENT ASSESSMENT

The maintenance of continence is a complex process involving an interrelationship between intestinal function, rectal sensitivity and compliance, and anal sphincter function. This in turn depends upon the integrity of sensory and motor neural pathways and the sphincter musculature itself. The anal sphincter complex comprises two muscles—an inner circular smooth muscle maintaining constant tone to prevent incontinence during sleep and largely responsible for resting anal canal tone (the internal sphincter) [14] and an outer striated muscle under voluntary control that can be contracted to defer defecation when appropriate (the external sphincter) [15].

History

Careful questioning can give a clue to the etiology of incontinence. A change in bowel habit to increased frequency and looseness may precipitate anal incontinence and could be suggestive of underlying colorectal disease. Urgency of defecation with reduced warning time (sometimes to only a few minutes) indicates loss of voluntary muscle control and suggests damage to the striated external anal sphincter or its nerve supply. Similarly, incontinence associated with vigorous activity or coughing suggests a deficiency of external sphincter function. Incontinence occurring between episodes of defecation with no call to stool, or the involuntary passage of flatus, indicates a poor anal canal resting tone and suggests damage or degeneration of the internal sphincter muscle. Inability to discriminate solid stool from flatus suggests damage to anorectal sensory pathways. Seepage or perineal soiling may be seen in situations where there is distortion of the anal canal by scarring or in the presence of a fistula. A careful medical history should be taken with specific attention to colonic function, previous anorectal surgery, and any potential causes of anal incontinence. An obstetric history should include details of birth weight, mode of delivery, length of labor, instrumental delivery, and details of any perineal trauma. Scoring systems, such as the St. Marks score [16] (Table 62.2), Wexner score (also known as Cleveland Clinic Florida Incontinence scoring system) [17], and Birmingham Bowel and Urinary Symptoms questionnaire (BBUSQ-22) [18], may be used to quantify anal incontinence and for audit or research [16]. Disease-specific quality of life scores (Fecal Incontinence Quality of Life Score [FIQL] [19]) can be used to assess various psychometric domains: lifestyle, coping/behavior, depression, and embarrassment. The FIQL has also been translated into different languages, which have been used worldwide [20–22]. These scores can be used to assess treatment outcomes in both research and service settings.

Examination

Physical examination should include inspection of the perineum, noting scarring from previous surgery or obstetric trauma. Voluntary contraction of the external sphincter can be seen and defects in the sphincter may be observed. Gaping of the anus at rest or on gentle perineal traction suggests a low resting tone and impaired internal anal sphincter function. Descent of the perineum at rest with accentuation on straining suggests pelvic floor weakness, pudendal neuropathy, or both. Straining may also reveal an unsuspected rectal prolapse. Perineal sensation can be tested by light touch and pinprick. Digital examination will allow crude assessment of resting anal tone and voluntary squeeze pressure, and any sphincter defects may be palpable.

Investigation

Special investigations can provide useful information in the management of women with incontinence (Table 62.3). Presentation with new anal incontinence, particularly in middle age, may be precipitated by a change in frequency or consistency of stool. Routine examination of the colon by barium enema or colonoscopy should be carried out to detect the presence of colonic pathology such as neoplasia or colitis. Clinical assessment of the pelvic floor and anal sphincters should be combined with anorectal physiological studies. Manometry allows measurement of functional anal canal length and of the resting and squeeze pressures. These provide objective evidence of internal and external anal sphincter function, respectively [23]. Anal canal sensation can be tested using a stimulating electrode and may be transiently impaired by vaginal delivery. Rectal sensation and compliance are usually measured by balloon distension. It is important that the rectum is compliant for preservation of continence. Inflammatory bowel disease, radiation proctitis, rectal prolapse, and diabetes can affect the rectal capacity and compliance. Measurement of PNMTL assesses pudendal nerve function by stimulating the pudendal nerve on each side and measuring the evoked response in the external anal sphincter [24]. Normal latencies do not necessarily exclude pudendal nerve damage since it may require 75% of the nerve to be disrupted to prolong the latency.

Table 62.2 St Mark's Incontinence Scoring System

	Never	Rarely (<1/month)	Sometimes (<1/week)	Usually (<1/day)	Always (daily)
Solid	0	1	2	3	4
Liquid	0	1	2	3	4
Gas	0	1	2	3	4
Lifestyle	0	1	2	3	4
Need to wear plug/pad/change underwear for soiling				No	Yes
				0	2
Taking constipating medicine				0	2
Lack of ability to defer defecation for 15 minutes				0	2
Total score = /24

Table 62.3 Investigations for Anal Incontinence

Investigation	Information

Imaging/structural	
Colonoscopy/barium enema/sigmoidoscopy	Underlying colorectal pathology precipitating or contributing to incontinence
Endoanal ultrasound (EAUS)	Integrity of internal and external anal sphincter
	Thickness of internal anal sphincter
	Fistulae
Magnetic resonance imaging (MRI)	Integrity of internal and external anal sphincter
Functional	
Manometry	Resting anal canal pressure
	Voluntary squeeze pressure
	Involuntary squeeze pressure
	Functional anal canal length
Rectal sensation and compliance	Rectal hypo/hypersensitivity
	Normal or reduced compliance
Pudendal nerve motor terminal latency (PNMTL)	Damage to pudendal nerves

Endoanal ultrasonography (EAUS) has revolutionized the understanding of anal canal anatomy (Figures 62.1 and 62.2). Both the internal and external anal sphincters can be visualized and EAUS is the investigation of choice for detection of defects in these sphincters [25]. The detection of sphincter defects enables clinicians to select women to undergo surgical sphincter repair, and the accuracy of EAUS for detecting sphincter disruption has been validated by correlation with operative findings [26]. Abnormal thinning of the internal sphincter can be measured accurately using EAUS; this may be indicative of idiopathic degeneration, whereas thickening of the muscle may be associated with prolapse syndromes.

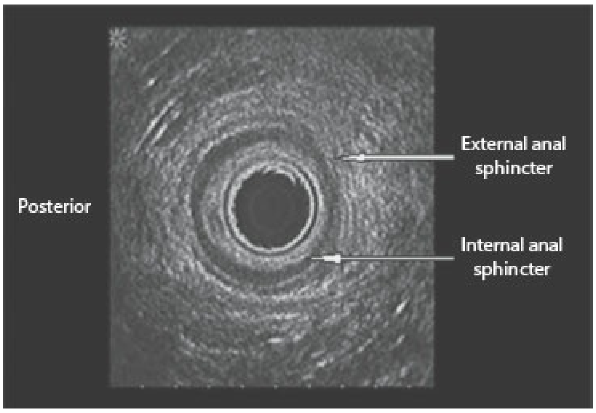

Figure 62.1 Normal endoanal ultrasound immediately postpartum.

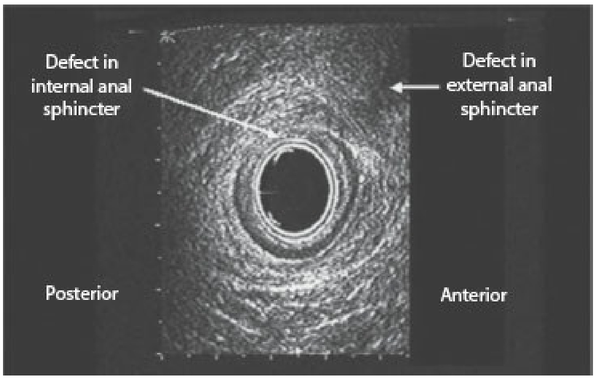

Defect in internal anal sphincter
Defect in external anal sphincter
Posterior
Anterior

Figure 62.2 Defects in internal and external anal sphincters.

Magnetic resonance imaging (MRI) using an endoanal coil provides excellent multiplanar views of the sphincter complex and can demonstrate defects in both the internal and external anal sphincters. It is probably most useful in identifying abnormalities in the external anal sphincter, the outer border of which may be difficult to visualize using EAUS. Expertise in MRI of the sphincters is not widely available and most clinicians continue to rely on EAUS. Where both imaging facilities are available, one or both may be used for diagnosis since they are complementary. Interest in functional MRI in the wider context is increasing; however, the lack of standardization of nomenclature has limited current understanding.

MANAGEMENT

Early Recognition of Obstetric Injuries

Evidence of sphincter injury should be sought by careful bimanual examination in all women who have a perineal tear or who have had an instrumental delivery. This should be carried out by someone trained in the recognition of sphincter injury. In the United Kingdom, there are a number of courses specifically for training obstetricians in the identification and management of obstetric sphincter injuries. An adjunct to bimanual examination is the use of EAUS in the delivery suite immediately postpartum. This is acceptable to women and can be used to diagnose sphincter injury and to assess the integrity of any repair [27]. Once recognized, repair of a sphincter injury should be carried out by someone adequately trained to do so, in an operating theater under regional or general anesthetic. Training in repair of sphincter injury should be part of the obstetric training program as the adequacy of sphincter repair is related to the experience of the operator [28]. At postnatal follow-up visits, women should be asked directly about anal incontinence as they are about other postpartum symptoms. Increased general awareness of the risk of postobstetric sphincter injury among midwifery and obstetric staff will also aid in the early diagnosis and treatment of anal incontinence. Early follow-up in a multidisciplinary clinic of women who have sustained obstetric trauma further increases the recognition of residual sphincter injury and enables effective early intervention where necessary [29].

Conservative Therapy

For most women, symptoms are relatively minor and should be managed conservatively, interventional procedures being reserved for those women with severe symptoms or in whom conservative measures fail.

Lifestyle

Attention to diet or the addition of a bulking agent such as ispaghula husk can improve symptoms in some individuals. Encouraging a daily routine for defecation may also help. The use of barrier creams such as zinc oxide ointment to prevent excoriation of perianal skin as a result of stool leakage is encouraged. High-fiber and a low-fat diet may help to prevent loose stools, which is a recognized risk factor of fecal Incontinence (FI) [30]. In a cross-sectional study of over 64,000 elderly women, high BMI, lack of physical activity, and cigarette smoking were identified as modifiable risk factors [31].

Drugs

Antidiarrheal agents such as codeine phosphate, loperamide, or diphenoxylate plus atropine reduce colonic motility and thus increase fluid absorption, producing more manageable formed stools. However, their side effects may include nausea, constipation, and abdominal cramping. The use of enemas or rectal washouts may help some women. The enema induces a bowel action and keeps the rectum empty between bowel movements.

Amitriptyline at low dose may be of benefit for some women with anal incontinence. Study has demonstrated its value, particularly for those with fecal urgency and increased rectal sensitivity by increasing transit time and decreasing the amplitude and frequency of rectal motor complexes, respectively [32].

There have been some reports of duloxetine hydrochloride helping women with fecal incontinence. Whether in the future this represents a viable treatment option remains to be seen.

In a Cochrane review on drug treatment for fecal incontinence in adults, the authors concluded that most of the drugs currently used are for the treatment of diarrhea rather than fecal incontinence, which may be due to the heterogenous nature of the FI population within the review [33].

Biofeedback

Biofeedback therapy can be helpful for some women with anal incontinence who are refractory to lifestyle and drug therapy. It is a behavioral technique using physical retraining of the anal sphincter and pelvic floor muscles with or without the aid of equipment, which provide auditory or visual feedback to alter physiological events [34]. The technique uses electromyography, where a sensing device monitoring external sphincter contraction is connected to a transducer producing an audio or visual response for the woman. The audiovisual record of sphincter activity assists the woman in recognizing strength and length of contraction. Using a balloon to distend the rectum, women are encouraged to improve sphincter contraction in response to decreasing rectal distension, so that over a period of time their response becomes automatic. These techniques are most useful for women who are well motivated, have some rectal sensation, and are able to contract the external sphincter voluntarily. Interestingly, results of investigative workup for fecal incontinence such as anorectal manometry, defecating proctogram, EAUS, MRI, and PNMTL do not predict the responders to biofeedback [35].

In a series of 100 patients treated with biofeedback, 43 regarded themselves as cured and 24 symptomatically improved [36], 27 of the 46 patients in this series with structural sphincter damage also reported cure or improvement.

Biofeedback is initially labor intensive, requiring a dedicated therapist, but can be carried out at home after training. It has the advantage of being painless, safe, and complementary to other interventions. Biofeedback training has been shown to improve functional outcome for women with persistent symptoms following sphincter repair [37]. However, some studies have suggested that it is the therapist rather than the technique that is important to the outcome [38].

Anal Plug

Containment may be improved by the use of a disposable anal plug or tampon to enhance continence. The device expands after insertion and is removed to allow evacuation. Use of the anal tampon has been shown to improve continence scores and quality of life but only about half of patients found it comfortable to use on a regular basis [39]. It has a role for those with severe symptoms who are awaiting (or are unsuitable for) surgery.

SURGERY

For some women, conservative therapies will fail and surgical options need to be considered. Two categories of patients may be identified:

Group 1: Women with evidence of a sphincter defect
Group 2: Women whose sphincters are intact but weakened, secondary to denervation or muscle atrophy

In the first group, direct repair of the sphincter defect should be considered; in the second group, decision-making is more difficult, the surgical options are more varied, and the outcome is less predictable.

Sphincter Repair

Sphincter repair is the operation of choice where there is a single defect of the external anal sphincter, either alone or in combination with a defect of the internal anal sphincter. Two different surgical techniques have been used: direct apposition and overlapping repair. In the context where the cause of sphincter defect is due to previous obstetric trauma, then almost all are located anteriorly and a third of them will develop symptoms of FI over time [40].

Sphincter repair by mobilization of the sphincter muscle, scar excision, and direct apposition resulted in a failure rate of around 40% [41], these poor results being attributed to the cutting out of sutures or retraction of the muscle ends. As a result, Parks and McPartlin subsequently modified this technique by identifying and repairing the torn internal anal sphincter separately and employing an overlapping repair of the muscle [42]. Authors using the former technique along with an end-to-end repair have reported a significant reduction in incontinence (up to 8%) [43]. Indeed, the results of two randomized controlled trials have shown both techniques to be similar [44,45].

Most studies seemed to be in favor of immediate rather than delayed repair for third- or fourth-degree tears following delivery. Although both immediate [46] and delayed repairs [47] have demonstrated good results, immediate repair would be more socially acceptable for the patient and delayed repairs should probably only be considered where expertise is lacking at the time of injury.

The need for a defunctioning stoma following sphincter repair has been studied and is only necessary where there is significant perineal sepsis. A temporary stoma confers no benefit in terms of functional outcome and is associated with higher morbidity and longer hospital stay related to the stoma closure [48]. Medical bowel confinement confers no benefit in terms of septic complications or functional outcome [49]. Prophylactic broad spectrum antibiotics are used to prevent infection, which may be linked to breakdown of the repair.

Review of published series shows that excellent or good results, with continence to solid and liquid stool, can be achieved in between 47% and 79% of patients undergoing sphincter repair [50–52]. The outcome data for overlapping sphincter repair should, however, be interpreted with caution for a number of reasons. Many of the reported series are small, with patients recruited over several years, often involving several different operating surgeons and follow-up tends to be short. The groups of patients reported are often heterogeneous in terms of age, sex, and indication for repair. The frequent absence of standardized scoring systems or physiological measurements to evaluate continence pre- and postoperatively does not allow series to be readily compared.

Outcome where there has also been damage to the internal sphincter is less certain. The importance of repairing the internal anal sphincter (when damaged) as well as the external sphincter has been highlighted during immediate repair of third-degree tears [53]. Such attention should probably also be applied to repairing a deficient internal anal sphincter during secondary repair. It is accepted, however, that internal sphincter defects may be more difficult to identify surgically and repair adequately, and soiling—together with incontinence to flatus—will remain a problem for some women.

Factors Predicting Outcome from Anal Sphincter Repair

A number of factors have been identified as predictive of outcome following anal sphincter repair.

Age and Body Habitus

Some authors have reported an adverse influence of increasing age on outcome [54]. Although older age is not a contraindication to surgery [51,52], it should certainly be considered in preoperative counseling when discussing outcome. Obesity has also been recognized to worsen outcome following repair of anterior anal defects [54].

Pudendal Neuropathy

Prolonged PNMTL (unilateral or bilateral) have been shown by some to be predictive of a poorer outcome after sphincter repair [55]. Although this finding may be useful in counseling women preoperatively, it should not necessarily be used to deny a woman operative correction of an obvious sphincter defect.

External Sphincter Atrophy

The detection by MRI scanning of atrophy of the external anal sphincter, which is characterized by thinning and fatty replacement, has been shown to adversely affect outcome following sphincter repair [56].

Failure of Sphincter Repair

Up to 10% of repairs may break down, resulting in persistent defects and poor functional results. Where such defects are identified, repeated sphincter repair may be successful [57]. Since the operation may be technically more difficult and tissue quality poor, the outcome following repeated sphincter repair is less certain. Where failure has resulted from significant perineal sepsis, a temporary defunctioning colostomy may be required and should be considered.

Long-Term Outcomes after Sphincter Repair

In a 5-year follow-up study of incontinent women who had an overlapping repair for obstetric trauma, only 4 out of 38 were totally continent of solid and liquid stool and none was fully continent of stool and flatus [58]. The overall success of the overlap method deteriorated with time. Whether the deterioration was due to progressive denervation of mobilized muscle or failure to repair internal sphincter defects adequately is uncertain. We however believe that sphincter repair remains the standard first approach for isolated defects, particularly in women presenting soon after obstetric injury [53]. These women should be made aware that initial good results may not be permanent and that deterioration in continence may occur in the future.

Postanal Repair and Total Pelvic Floor Repair

The operation of postanal repair (PAR) aims to restore an adequate anorectal angle, which is of theoretical importance in maintaining continence. The long-term results from PAR are poor, with only a third of women maintaining continence at 5-year follow-up. Total pelvic floor repair (TPFR) combines PAR with anterior sphincter plication and anterior levatoroplasty. Long-term follow-up indicates that TPFR rarely renders women fully continent, but around half have substantially improved continence and lifestyle [59].

The poor long-term success rates reflect progressive neuropathy or atrophy of the muscles and have led to a move away from PAR and TPFR as surgical options. These operations are, however, associated with low morbidity and thus may still have a role for women with significant symptoms who are unsuitable for more complex reconstructive procedures or who refuse a stoma.

Alternative Surgical Techniques

For women with symptomatic anal incontinence but an intact sphincter confirmed by imaging, other surgical options can be considered.

Sacral Nerve Modulation

A novel approach to women with incontinence and weak but intact internal and external sphincters is to modulate the neurological control of the anorectum. Sacral nerve modulation (SNM) (Figure 62.3.) was initially used in patients with detrusor instability and urinary retention in the 1980s [60]. The observation of a simultaneous improvement in bowel symptoms in some of these patients led to its use by Matzel et al. in patients with anal incontinence in 1995 [61].

SNM involves chronic low-frequency electrostimulation of one of the sacral spinal nerves (S2, S3, or S4). The mechanism of action of SNM is uncertain: studies have demonstrated that SNM not only modifies somatic and autonomic nervous functions [62], but also central nervous system activity [63]. However, the effect of SNM on the anal sphincter is inconsistent as some authors reported an increased anal resting tone and maximum anal squeeze pressure while others reported the contrary [64–66]. Clinical studies on SNM have demonstrated improvement in continence in patients with external sphincter defects, suggesting the sphincter mechanism is not solely responsible for maintaining continence [67]. The effects of SNM on rectal sensitivity and compliance are also unclear and conflicting [64,68,69]. Possible reasons include small sample size and the heterogeneous etiology of anal incontinence within sample groups. Anorectal physiological studies do not appear to be a useful predictor of outcome for SNM.

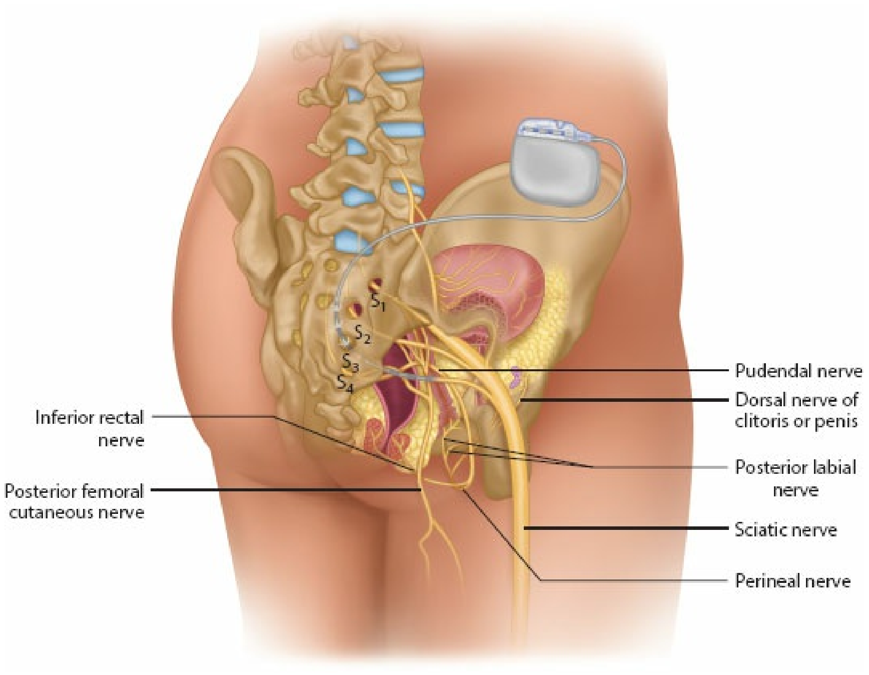

Figure 62.3 Relationship between position of sacral nerve stimulation device and relevant anatomy. (Courtesy of Medtronic, Inc., Minneapolis, MN Copyright 2010.)

A major advantage of SNM is that it involves placement of a temporary electrode, which can be used over a 1–4 week test period to measure response prior to embarking on surgical implantation of the permanent device. Following the initial trial, 60%–88% of patients proceed to permanent implantation [70–72]. A further advantage of SNM is that it does not involve any risk of direct surgical trauma to the sphincter mechanism itself. Morbidities associated with the procedure are less compared with other surgical techniques with a reported incidence ranging from 5% to 26% [62]. Such morbidities are usually minor and include pain at implant site, seroma, excessive tingling in the vaginal region, and superficial wound infection [62].

A meta-analysis published in 2011 of 665 patients who underwent SNM versus conservative treatment on patients with fecal incontinence found that the SNM group had reduced incontinence episodes, increased ability to defer defecation and improved quality of life scores [73]. A randomized controlled study by Tjandra et al. has demonstrated SNM to be more effective than optimal medical therapy, with the SNM group reporting significantly fewer incontinent episodes per week (from 9.5 to 3.1) and incontinent days per week (3.3 to 1) compared to controls (from 9.2 to 9.4 and from 3.3 to 3.1 respectively) [72]. Within the same institute and population sample, Chan et al. also demonstrated that SNM improved continence in patients with external anal sphincter defects of up to 120° of circumference [67].

Data on the long-term studies of SNM, with a mean follow-up of 51 to 74 months, have found a sustained improvement of fecal incontinence score and quality of life score [71,74,75]. In the national registry of the Italian group of sacral nerve stimulation, Altomare et al. [71] reported follow-up of 52 patients over a mean period of 74 months (range, 60–122). The group originally had 60 patients but 2 patients died of nonrelated disease to anal incontinence, and 6 had the device removed due to persistent complications or progressive failure of therapeutic efficacy within the first 2 years of follow-up. Hence 52 out of 60 (86.7%) patients were available for review. Out of 52 patients, 15 (28.8%) continued to suffer from complications, which included pain at site of implant (11.5%), electrode displacement (15.4%), and early battery rundown (1.9%). Functionally, by comparing Wexner scores at both baseline and follow-up for 50 patients, the mean score decreased from 15 to 5. In this study, 9 patients (18%) achieved 100% continence, 25 (50%) achieved at least 75% continence, and 37 (74%) achieved at least 50% continence. Matzel et al. [76] reported the follow-up of nine patients with a minimum of 7 years and mean period of 9.8 years (range 7–14). Compared to preoperative results, accidental loss of bowel content reduced from 40% to 0%, median number of incontinence episodes/week from 9 to 0.4 out of the 9 (44.4%) patients remained fully continent. A study carried out by Hollingshead et al. has even found no loss of efficacy in three patients after a 10-year follow-up [77].

Posterior Tibial Nerve Stimulation

Posterior tibial nerve stimulation (PTNS) (Figure 62.4) is an alternative technique of neuromodulation to SNM. It is a new concept that requires the application of electrical stimulation either percutaneously or transcutaneously, unilaterally over the posterior tibial nerve (located above and behind the medial malleolus). Currently, there are various protocols for the treatment with PTNS (e.g., one protocol involves 30 minutes per session, once a week for 12 weeks) [78–80]. Overall efficacy of PTNS ranges from 20% to 100%. Such wide range of results reflects on the heterogeneous nature of the study population, the different types of applications and the protocol used. Currently, a multicenter, randomized trial, CONFIDeNT (ISRCTN88559475), is ongoing with the primary end-point being a reduction in weekly fecal incontinence episodes and the secondary end-points being improvements in validated incontinence scores and disease-specific quality of life measures.

Neosphincters

Muscle Transposition

It is possible to augment the anal sphincter with another striated muscle. The muscles most commonly used are gracilis or gluteus but others such as obturator internus have also been employed [81]. Graciloplasty involves mobilization of the muscle from the inner thigh, which is wrapped around the anal canal and fixed to the contralateral ischial tuberosity. Continence is reliant upon the muscle wrap being tight enough to keep the anal canal closed, as coordinated voluntary contraction of the muscle itself is difficult. Gluteus transposition is a technically more demanding procedure but has the advantage that the muscles are easier to contract since the glutei are natural synergists of the anal sphincter. Results of unstimulated muscle transposition vary widely and it is now a rarely used technique. Bilateral graciloplasty may be useful where lack of local technical expertise or financial resources do not allow stimulated transposition.

Stimulated Muscle Transposition

The observation that by chronic stimulation muscle fibers could be converted from type II fast-twitch to fatigue-resistant slow-twitch fibers led to the development of the stimulated graciloplasty [82]. The mobilization of the gracilis muscle and wrap are similar to that for unstimulated graciloplasty but involve identification of the nerve to gracilis and implantation of a stimulating electrode around the nerve trunk or its branches. The stimulator is placed in a subcutaneous pocket in the abdominal wall and the electrode wires tunneled to it. After satisfactory healing, a period of muscle stimulation is commenced until continuous stimulation results in sustained muscle contraction. The patient switches off the stimulator to allow the muscle to relax and enable defecation [83]. Contraindications to stimulated graciloplasty include a history of perianal sepsis or Crohn's disease. In addition, as the stimulator may interfere with pacemakers and implanted defibrillators, the technique may not be appropriate in these patients.

In a study of 52 patients undergoing stimulated graciloplasty, 73% were continent after a median follow-up of 2 years and success was associated with improved quality of life [83]. Others have reported far less favorable results. Septic complications, hardware problems, and physiological imbalance have led to the high failure rates reported in some series [81]. Case selection is important; patients need to be well motivated and require careful preoperative assessment and counseling. The procedure has a recognized failure rate and may be associated with significant morbidity and scarring. In addition, patients may require significant input in terms of support for fine-tuning the stimulator.

Artificial Bowel Sphincter

When the sphincter muscles are irretrievably damaged or previous attempts at reconstruction have failed, the use of an artificial bowel sphincter may provide a simpler and less invasive approach than stimulated muscle transposition. The artificial sphincter prosthesis was developed from use in the treatment of urinary incontinence. It comprises a cuff that is implanted around the anus and a pressure-regulating balloon that is placed behind the rectus muscles and connected to a pump placed in the subcutaneous tissues of the labia. A temporary colostomy is not normally required. Cuff opening is controlled by squeezing the labial pump that then empties the cuff to enable evacuation; the cuff then slowly refills from the pressure-regulating balloon over a number of minutes to close the anal canal. Contraindications for artificial bowel sphincter include active sepsis, previous radiation, Crohn's disease, and poor-quality perineal tissue [84].

Early reports of the purpose-designed artificial bowel sphincter indicated that excellent functional results can be achieved both in terms of improving continence scores and improving anal canal resting pressures without adversely affecting rectal function [85]. An audit of the UK experience, however, showed that two-thirds of the sphincters implanted had required removal [86]. Infection was the predominant cause and methicillin-resistant *Staphylococcus aureus*, a common pathogen. Despite good functional outcomes in a proportion of patients, the future for the artificial sphincter remains uncertain. Early septic complications necessitate removal of the device in some patients and improvements in care directed at preventing infection are required. Long-term results reported by the Minnesota group demonstrated that only 49% of 45 patients achieved a functional artificial sphincter, with infection being the main reason for failure. Where implantation was successful, those patients did experience improved continence and quality of life [87].

Magnetic Sphincter

The use of a magnetic bead band for fecal incontinence aims to enhance the anal sphincter pressure by its weak magnetic force (Figure 62.5). During defecation, the increased intra-abdominal pressure allows the magnetic beads to separate, followed by reunion of beads to re-establish continence once stool is passed. The insertion of the titanium magnetic beads requires patient to undergo a general anesthetic. Under aseptic technique, an incision is made in the perineal body and a tunnel created along the circumference of the anal canal. The implant is then positioned after estimation with a sizing tool and secured by tying sutures together. Studies on its efficacy have so far been on either comparison study and case series [88,89]. In one comparative case-matched study, the magnetic anal sphincter was found to be as effective as the artificial sphincter in terms of improvement of incontinence and quality of life [89]. However, one case series reported suboptimal results with no patients reporting a clinical response (defined as >50% reduction in the Wexner score) and a morbidity rate of 57% [90]. Other case series found that some patients with an implanted magnetic anal sphincter can produce a sustainable result of up to 36 months [91]. Complications from magnetic bead sphincter include infection, bleeding, perianal swelling, separation at the suture connection, and pain [88–91].

Sphincter Augmentation

Endoscopic radiofrequency therapy (a.k.a. SECCA® procedure) aims to include fibrosis to the anal sphincter and thereby tightens its muscle fibers to improve fecal incontinence. It can be performed under general anesthetic or under sedation with a local anesthetic. Needle electrodes are guided to optimal position and deliver heat-generated radiofrequency energy at several sites of the anal sphincter with temperature monitoring to avoid excessive heat [92]. Although a good-quality trial is still awaited, several case-series studies have reported favorable short- and long-term results [93–95]. In terms of complications, there have been reports of secondary hemorrhage, constipation, anal pain, and mucus discharge after the procedure [96,97].

Injectable Bulking Agents

The use of injectable bulking agents was first described by urologists for urinary incontinence. The technique of mechanical bulking of the anal sphincter has been used for fecal incontinence since 1993 [98]. There are various injectable bulking agents: Coaptite (calcium hydroxylapatite ceramic microspheres), Contigen (collagen implant), Durasphere (pyrolytic carbon-coated beads), EVOH (Ethylene Vinyl Alcohol), polyacrylamide gel (Bulkamid), and PTQ (textured silicone particles). Injections are usually into the submucosal region or at the site of the sphincter defect. The morbidities described (generally low) range from pruritus ani, persistent anal discomfort to perianal sepsis [99]. A systematic review on the efficacy and safety of injectable bulking agents for passive fecal incontinence has found 13 case-series studies and only 1 randomized controlled trial. Although most studies reported statistical significant improvement in incontinence scores and quality of life, no statistical difference was found between the treatment and placebo arms in the randomized controlled trial [99].

Stomas

For some women who fail to respond to conservative or surgical treatments, a colostomy may be the only alternative to managing intolerable symptoms. In these individuals, a stoma should not be seen as a treatment failure and may allow many women to return to a near normal lifestyle. Colostomy irrigation is possible and may further improve their quality of life. Unfortunately, for a few women with a colostomy, persistent incontinence of mucus from the defunctioned rectum remains a problem and a proctectomy may be required.

SUMMARY

Careful assessment and investigation of anal incontinence can usually determine the underlying cause. Most women can be managed conservatively by a combination of dietary modification, medication, and biofeedback. Where conservative treatment fails, surgery may be considered. Women with identifiable sphincter defects may benefit from overlapping sphincter repair that offers good short-term functional results. Women should be counseled that longer-term results are less certain. When sphincter repair fails or where the sphincter itself is intact but weak, SNM and PTNS should be considered. Postanal repair, TPFR, and unstimulated muscle transposition offer short-term improvement for many women. Stimulated muscle transposition, artificial sphincters, magnetic bead band, SECCA® procedure, and injectables can provide a more satisfactory solution, but may be associated with associated morbidity. For a few women who have failed all treatment modalities, diversion stomas may be recommended.

63 Constipation

Kaori Futaba, Yvette Perston, Tony Mak, and Simon Radley

INTRODUCTION

"Constipation" is usually understood to imply infrequent bowel evacuations or difficult passage of feces persisting for a few weeks. It is one of the commonest medical complaints affecting patients of all ages, with an estimated UK prevalence varying from 8.2% to 52% [1]. Its incidence increases with age and is higher in those of lower socioeconomic class and with lower educational status [2].

The causes of constipation are multifactorial. These include dietary factors, toileting habits, medications, underlying medical conditions, psychological problems, organic diseases of the gastrointestinal tract (Table 63.1), and failures of the defecatory process [3]. Accurate history and clinical examination and investigations are essential in identifying a cause for each patient's symptoms.

PHYSIOLOGY OF NORMAL DEFECATION

Effective defecation requires coordinated efforts of colonic motility, intact rectal sensation, and pelvic floor relaxation. The primary function of the colon is the absorption of water from the small bowel effluent, leaving 100–150 mL of water in feces. A secondary function is to enable bacteria to ferment undigested fiber; the rectum stores feces until defecation takes place. Normal colonic transit varies from 24 to 96 hours [4].

The colon, rectum, and internal anal sphincter (continuation of the smooth muscle) are extrinsically innervated by the autonomic nervous system. The sympathetic innervation via the coeliac, superior, and inferior mesenteric plexus and hypogastric nerves (T11–L2) inhibits peristalsis and are sensitive to distension. The parasympathetic innervation by preganglionic vagal fibers and S2–4 splanchnic nerves increases peristalsis, contracts rectum, and relaxes internal anal sphincter to assist defecation. The intrinsic enteric nervous system (submucosal and myenteric plexuses) influences contractions and tone while the cells of Cajal are pacemakers. Local hormones also play a role.

CLASSIFICATION OF CONSTIPATION

The Rome consensus group published the Rome III criteria defining functional gastrointestinal disorders (Table 63.2). In order to be considered of medical significance, symptoms must be present for at least 3 months with onset of symptoms 6 months before diagnosis [5].

Subtypes of Constipation

Constipation can be divided into the following subtypes:

1. *Motility disorder*: Decreased high-amplitude peristaltic contraction causing slow transit constipation. Patients with severe colonic inertia may have a more diffuse motility disorder [6].
2. *Obstructive defecation syndrome* (ODS) *[7]* (also known as pelvic outlet obstruction, anismus, and pelvic dyssynergy): characterized by sensation of incomplete evacuation, prolonged straining and need for digital manipulation.
3. Irritable Bowel Syndrome with Constipation (IBS-C) associated with abdominal pain, irregular bowel habits, and pain relieved by defecation.

These subtypes of constipation can coexist.

HISTORY

"Constipation" implies different things to different people. An accurate history from the patient is important and should include size, consistency, and frequency of defecation and duration of symptoms.

In a UK-based population study, 99% of healthy individuals (*n* = 1455) had between three bowel motions per day to three times per week [8]. The Bristol stool chart is helpful in describing consistency [9]. The presence of mucus or blood in or on stool and history of abdominal or perianal pain should be ascertained as well as any difficulty in evacuation, need for perineal pressure, or digitation vaginally or rectally. Patients with slow transit constipation may complain of infrequent bowel movements and lack of urge to defecate despite laxatives. IBS patients may present with a chronic relapsing abdominal symptoms including abdominal pain and bloating associated with disturbed bowel habit [10].

If the patient has any of the red flag symptoms or signs (Box 63.1), they should be referred to a colorectal surgeon for further assessment to exclude colorectal cancer as per NICE guidance before proceeding to any further treatment [11].

Patients may have additional symptoms of urinary dysfunction or symptoms of uterine or vaginal prolapse, implying more global pelvic floor abnormality and dysfunction. It is important to ascertain if a patient has had a hysterectomy. Patients often date back the onset or exacerbation of symptom to that time [12]. A thorough obstetric history may reveal a history of obstetric trauma; high vaginal parity; prolonged labor, which may be associated with uterine prolapse; enteroceles; rectocele; and descending perineal syndrome. These conditions may present as symptoms of obstructive defecation such as prolonged defecation with sensation of anorectal obstruction and rectal fullness with tenesmus; as such these are also important screening parts of a urogynecological or urological history. Women sometimes use vaginal, anal digitation, or perineal pressure to aid evacuation.

Table 63.1 Causes of Secondary Constipation

1. General		
Poor diet ± lack of exercise		
Poor fluid intake/dehydration		
Old age		
Postoperative pain		
Hospital environment (lack of privacy/use of bed pan)		
2. Medication (BNF)		
Drug Group	*Condition*	*Examples*
Opiate	Pain control	Codeine, morphine, fentanyl
Antimuscarinic	Overactive bladder	Oxybutynin, solifenacin
	Parkinson’s disease	Procyclidine, benzhexol
	Asthma	Ipratropium
Tricyclic antidepressant	Depression	Amitriptyline, dothiepin
Antipsychotics	Schizophrenia	Chlorpromazine, clozapine
Parasympathomimetic alkaloid	Xerostomia/Sjögren’s	Pilocarpine
Vinca alkaloids	Leukemia/lymphoma	Vincristine, vinblastine
Calcium channel blocker	Arrhythmias/hypertension	Verapamil
Diuretics	Heart failure	Furosemide
Antacids	Indigestion	Calcium/aluminum + antacids
Supplements	Iron deficiency anemia	Ferrous sulphate
	Osteoporosis	Ergocalciferol
Nicotine replacement	Aid smoke cessation	Nicotine lozenges
3. Metabolic/endocrine conditions		
Amyloid		
Glucagonoma		
Hypercalcemia (hyperparathyroidism, milk alkali syndrome)		

    - Hypothyroidism
    - Hypokalemia
    - Panhypopituitary syndrome
    - Pheochromocytoma
    - Pregnancy
    - Porphyria
    - Arsenic/mercury/lead/phosphorus poisoning
    - Uremia

4. Bowel disorders
    - *Obstruction*: colorectal cancer, Crohn’s stricture, diverticular disease, volvulus
    - Pelvic mass (e.g., fetus, fibroid)
    - Fecal impaction
    - Megacolon/rectum
5. Neuromuscular conditions
    - *Central disorder*: tumors, trauma, cerovascular
    - *Peripheral disorder*: von Recklinghausen’s disease, multiple endocrine neoplasia
    - Spinal or pelvic nerve injury (e.g., obstetric trauma, surgery)
    - Aganglionosis (Hirschsprung’s and Chagas’ diseases)
    - Systemic sclerosis
    - Multiple sclerosis
    - Parkinson’s disease
    - Diabetic neuropathy
    - Pan gut dysmotility
6. Psychogenic
    - Anxiety/depression
    - Obsessional personality
    - Sexual/physical abuse
    - Immobility
    - Anorexia nervosa, bulimia, eating disorder

Table 63.2 Rome III Criteria for Functional Constipation and Irritable Bowel Syndrome with Constipation

Functional constipation	**Irritable bowel syndrome**
Must include at least two of the following: • Straining[a] • Lumpy or hard stool[a] • Sensation of incomplete evacuation[a] • Sensation of anorectal blockage[a] • Manual manoeuvres to facilitate defecation [a]* (digital evacuation, support of the pelvic floor) • <3 stools per week Loose stools rarely present without the use of laxatives. Insufficient criteria for irritable bowel syndrome.	Recurrent abdominal pain or discomfort for at least 3 days/month in the last 3 months associated with at least two of the following: • Improvement with defecations • Onset associated with a change in frequency of stool • Onset associated with a change in form of stool IBS-C is a subtype of IBS with Bristol stool chart type 1–2 in ≥25% of defecations and type 6–7 in ≤25% of defecations.

Source: Tattersall MH, *Lancet Oncol*, 7(11), 886, 2006.

[a] At least 25% of defecations.

Box 63.1 Red Flag Symptoms and Signs of Colorectal Cancer

Change in bowel habit to looser stools or increased frequency and rectal bleeding (>40 years old)
Persistent rectal bleeding for 6 weeks without anal symptoms (>60 years old)
Change in bowel habit to looser stools or increased frequency for 6 weeks (>60 years old)
Palpable right iliac fossa mass
Palpable rectal mass (intraluminal)
Unexplained iron deficiency anemia (Hb < 11 g/dL for men and Hb < 10 g/dL in nonmenstruating women)

Initial treatment is based on lifestyle advice, and therefore, it is also mandatory to ascertain information on diet, fluid intake, exercise habits, and medical, surgical and drug histories, as drug side effects may precipitate symptoms.

Pelvic floor dysfunction is often associated with depression and anxiety, so questioning about additional contributing factors such as psychiatric illness and any history of sexual abuse may yield important information that may modify treatment regimens [13,14].

Patients with constipation may also report an increased incidence of history of sexual and physical abuse and a poorer health status than the general population [15]. In a study of 118 constipated patients, 32% reported physical abuse and 22% sexual abuse [16]. It is important that the issue of abuse is explored with appropriate backup from a safeguarding team where required. Patients often report that their bowel problems have adversely affected their family life, their relationships, work, and social life [16]. In a cross-sectional survey, Sun et al. [17] found that individuals with chronic constipation compared with matched controls were more likely to take sick leave and report general health impairment affecting work performance.

CLINICAL EXAMINATION

Abdominal examination may be unremarkable in most patients but it is important to rule out any intra-abdominal masses. Rectal examination is mandatory looking for skin tags, anal fissures, external hemorrhoids, and excoriation if present. Gaping of anal opening may suggest an underlying neurological problem or a full-thickness rectal prolapse. It is important to check for altered sensation around the perianal skin and perineum. A lack of reflex contraction of the external anal sphincter to perianal stimulation may indicate impaired pelvic innervation. Patients may demonstrate a full-thickness rectal prolapse, a bulge into the vaginal introitus indicating a rectocele, or bulging of the perineum below the ischial tuberosities indicating perineal descent. Digital rectal examination is performed systematically to assess resting anal tone; squeeze pressure by asking the patient to clench their anus on the examining finger. The finger is swept clockwise and anticlockwise to examine the entire circumference of the anal canal feeling for masses, ulceration, and tenderness. The puborectalis is examined by hooking the finger posteriorly over the coccyx. The puborectalis should be relaxed when the patient is asked to strain. In patients with anismus or dyssynergia, the puborectalis muscle often fails to relax or may be felt to contract when they strain. The sensitivity and specificity of diagnosing dyssynergia on rectal examination are 75% and 87%, respectively, when two or more of the following are identified on rectal examination: impaired perineal descent, paradoxical anal contraction, or impaired push effort [18]. Rigid sigmoidoscopy or proctoscopy examination in clinic can be a useful adjunct in assessing any mucosal abnormality in the anus and rectum as well as assessing rectoanal intussusception; mucosal folds may be visible when prominent. If there is a history of vaginal prolapse or obstructed defecation, vaginal/pelvic examination should also be performed.

INVESTIGATIONS

Systematic review looking at clinical utility of diagnostic tests for constipation however showed no clear evidence to support performing routine blood test, radiography, and endoscopy in patients with constipation without “red flag” symptoms [19,20]. So while screening for metabolic cause of constipation with full blood count and biochemistry including calcium and thyroid function test, this should be reserved for new patients presenting with constipation where there is a high index of suspicion or a relevant medical history. A meta-analysis of prospective cross-sectional surveys and cohort studies demonstrated no increase in prevalence of colorectal cancer in patients with constipation [21]. Patients with red flag signs or concerns about intraluminal cause for their symptoms should have endoscopic (flexible sigmoidoscopy/colonoscopy) or radiological examination (CT colonography/contrast study).

Additional investigations are reserved for patients who fail simple medical therapy. A modified algorithm of the management of constipation by the American Gastroenterological Association is shown in Figure 63.1 [22].

The following tests are useful in distinguishing between normal, slow-transit constipation, and ODS. Pros and cons of each investigation are summarized in Table 63.3 [19].

Diagnostic Studies to Evaluate Anorectal Function

Balloon Expulsion Test

This is a simple bedside test performed to assess the patient’s ability to expel an artificial stool. A balloon is placed in a patient’s rectum and filled with water. The patient is then asked to expel the balloon. Normal expulsion time is within a minute. Although a failure to expel a 50 mL balloon suggests dyssynergia, a normal test does not exclude the diagnosis [20].

Anorectal Manometry

This provides comprehensive information regarding rectal sensation, rectoanal inhibitory reflexes (RAIRs) and anal sphincter function. Anorectal manometry is a useful test for diagnosing dyssynergy (Figure 63.2) and altered rectal sensation and helps identify patients who may be suitable for biofeedback therapy [19]. A catheter-mounted balloon is inflated incrementally to

1. First constant sensation
2. Desire to defecate volume
3. Maximum tolerated volume

The three simple sensory thresholds described earlier cannot distinguish the factors influencing sensation including compliance and neural pathways [23]. Decreased sensation to distension is seen in obstructed defecation, but the evidence that this is due to parasympathetic nerve damage is debatable [24,25]. Damage to these nerves may be a factor in constipation following hysterectomy [26].

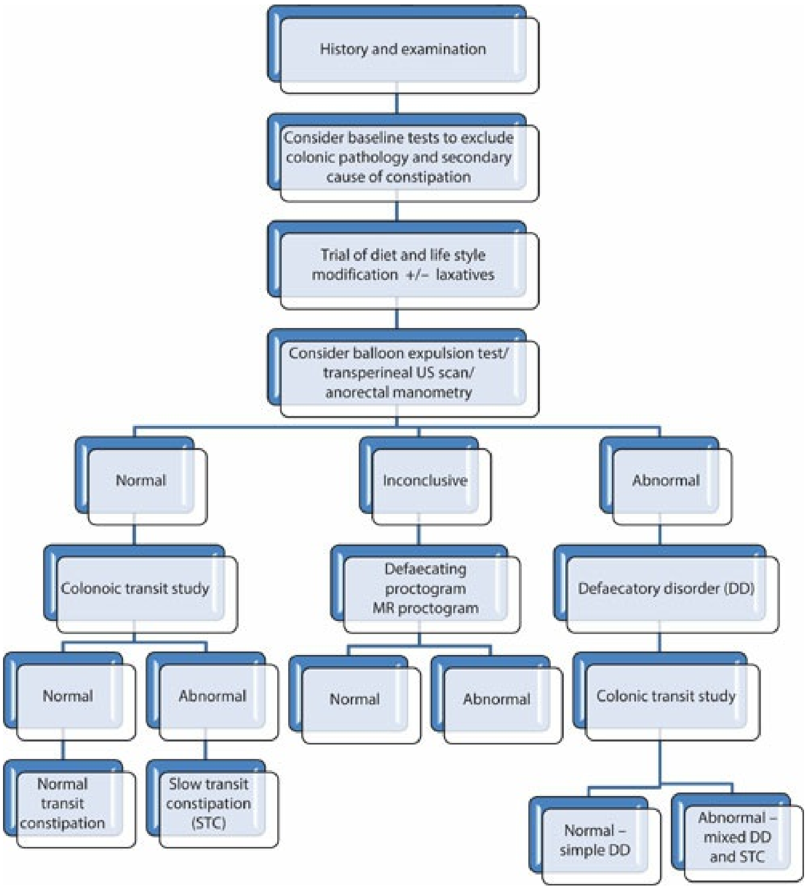
By using isobaric distension of a balloon, rectal compliance can be calculated as the steepest gradient of the curve plotting volume instilled divided by rectal pressure. Where compliance is high, greater volume needs to be instilled to achieve a given rise in pressure. This is the case in megarectum or in obstructive defecation. Decreased compliance (reduced laxity, increased hypersensitivity) is often found in inflammatory bowel disease or after pelvic radiotherapy.

RAIR is the reflex relaxation of the internal sphincter that occurs when a balloon is inflated in the rectum. Factors such as body position and consistency of “stool” play a role in one’s ability to expel stool. Up to 20% of asymptomatic healthy adults do not produce normal relaxation during attempted defecation [27]; hence, a finding of dyssynergia on anorectal manometry alone is not diagnostic. Electromyography (EMG) can also aid in the diagnosis of puborectalis syndrome where there is paradoxical or nonrelaxing puborectalis muscle.

Defecating Proctography

Defecating proctography is regarded as the gold standard investigation for evacuatory dysfunction. Contrast is inserted into the rectum, vagina, and small bowel to delineate each structure. The patient is asked to defecate on a commode under fluoroscopy to assess the process and effectiveness of defecation. Functional obstruction due to paradoxical contraction of puborectalis can be estimated by measuring the anorectal angle during defecation. Other causes of obstructive defecation such as rectocele, rectoanal intussusception, rectal prolapse, enterocele, sigmoidocele, vault prolapse, and excessive perineal descent can be identified. Small rectoceles may be physiological (Figure 63.3).

MR proctogram has the advantages of avoiding radiation and producing better anatomical and functional images of the pelvic floor anatomy, especially in patients who have had previous surgery [28,29] (Figure 63.4). A study comparing the results of defecating proctogram and MR proctogram in patients presenting with obstructive defecation symptoms found MR proctogram under reported pelvic floor abnormalities especially when there has been poor rectal evacuation [30]. This may be due to the fact that MR proctograms are often performed in a supine position with the patient defecating lubricating gel and patient found it difficult to evacuate in this nonphysiological condition [30].



History and examination
Consider baseline tests to exclude colonic pathology and secondary cause of constipation
Trial of diet and life style modification +/– laxatives
Consider balloon expulsion test/ transperineal US scan/ anorectal manometry
Normal
Inconclusive
Abnormal
Colonoic transit study
Defaecating proctogram MR proctogram
Defaecatory disorder (DD)
Normal
Abnormal
Normal
Abnormal
Colonic transit study
Normal transit constipation
Slow transit constipation (STC)
Normal – simple DD
Abnormal – mixed DD and STC

Figure 63.1 Investigation algorithm for chronic constipation. (Based on American Gastroenterological Association et al., *Gastroenterology*, 144(1), 211, 2013; modified.)

An MR-based classification for ODS has been described by Piloni et al. based on combinations of abnormalities found (Table 63.4) [31].

Ultrasound Scan

Transperineal or translabial ultrasound scans allow multiplanar real-time imaging of the pelvis, providing important information on the dynamic functional anatomy of the pelvic floor. It is reported to have excellent tissue discrimination, allowing visualization of modern mesh implants that are difficult to see in other modalities [32]. Transperineal ultrasound scanning may compliment the aforementioned defecography by providing more information on rectal compliance and movement [33].

Diagnostic Studies to Evaluate Intestinal Transit

Since patient recall of bowel habit is often inaccurate, it is helpful to have an objective measure of transit. In the general population, the colonic transit time is normally less than 72 hours [34]. Various modalities are now available to determine gastrointestinal transit time [35].

Transit Study Using Radiopaque Markers

A capsule containing 24 radiopaque markers is swallowed and abdominal radiographs are taken at 12 and 120 hours. Normal colonic transit is defined as >20% markers at 12 hours and <80% at 120 hours [36]. Alternatively, different shaped radiopaque markers are ingested at 0, 24, and 48 hours and an abdominal x-ray is taken at 120 hours [37,38] (Figure 63.5). By counting the number of different shapes remaining, a special formula is used to estimate the transit time. Patients are asked to have high-fiber diet (20–30 g/day) and avoid laxatives, enemas, or medications that affect the bowel during the study. Excessive retention of markers in the rectum may infer outlet obstruction, rather than slow transit; 60% of patients with dyssynergic defecation have excessive retention of markers [39].

Table 63.3 Evidence-Based Summary of the Clinical Utility of Diagnostic Tests for Chronic Constipation

Test	Pros	Cons	Evidence	Recommendation
Abdominal x-ray	Simple, widely available to identify excessive fecal loading	Lack of standardization	Poor	C
Barium enema	Identify megacolon/rectum, stenosis, diverticulosis, intraluminal abnormality	Radiation exposure	Poor	C
Shapes transit study	Evaluate colonic transit, inexpensive	Inconsistent methodology	Good	B2
Colonic transit with scintigraphy	Evaluate slow/normal/rapid transit	Expensive, time-consuming	Good	B2
WMC	Evaluation of upper and lower GI transit, no radiation	Variable availability	Excellent	A1
Defecating proctogram	Identify dyssynergia, rectocele, prolapse, excessive decent, Hirschsprung’s disease	Radiation exposure, interobserver bias, inconsistent, embarrassment	Fair	B3
MR proctogram	Evaluates pelvic floor anatomy, sphincter morphology, and dynamic motion	Lack of standardization expensive, variable availability	Fair	B3
Anorectal ultrasound scan	Visualization of anal sphincters	Interobserver bias, variable availability	Poor	C
Anorectal manometry	Identify dyssynergic defecation, rectal hyposensitivity/hypersensitivity, impaired compliance	Embarrassment	Good	B2
Colonic manometry	Identify colonic myopathy, neuropathy	Invasive, variable availability	Good	B2
Balloon expulsion test	Bedside assessment of dyssynergic defecation	Lack of standardization	Good	B2

Notes: Grade A1: excellent; Grade B2: Good; Grade B3: Fair; Grade C: Poor.
Evidence in favor of the test with some evidence on specificity, sensitivity, accuracy, and positive predictive values.

Gastrointestinal Transit Scintigraphy

Scintigraphy can be used to assess the whole gastrointestinal tract or colonic transit [35]. Liquid or solid labeled with ^{111}In or ^{99m}Tc is ingested and scanned sequentially over hours to assess gastric emptying and small bowel transit [40,41]. Colonic transit scintigraphy is used to measure regional colonic transit by swallowing a pH-sensitive capsule containing ^{111}In absorbed on activated charcoal that is released in the terminal ileum. This will clarify if the patient has diffuse or localized dysmotility [42]. Scintigraphy can be useful when considering surgical treatment.

WMC

A SmartPill wireless motility capsule (WMC) is ingested with pH, temperature, and pressure sensors allowing a noninvasive method of measuring gastric emptying and small bowel and colonic transit [43]. WMC may reduce the need for further invasive motility tests [44,45].

Colonic Manometry

Colonic manometry catheters are placed using a colonoscope or via guidewire. A 24 hour recording allows complete assessment of overall motor activity in the colon at rest, during sleep, while walking, and after meals and medication, which may be helpful in diagnosing underlying myopathy or neuropathy, especially in children [46].

TREATMENT

The majority of patients presenting to their GP will respond well to simple conservative measures such as dietary and lifestyle advice and laxatives. Patients with persistent symptoms who are referred to the tertiary referral centers will benefit from investigation to identify those with slow transit constipation, obstructive defecation, or normal transit/IBS-C and to guide treatment.

CONSERVATIVE MANAGEMENT

Dietary and Lifestyle Advice

In contrast to the traditional advice to increase fiber intake (fruit, vegetables, or wheat bran), Tack et al. [47] suggested that patients with slow transit constipation (STC) are unlikely to respond to increased dietary fiber. In addition, Muller-Lissner et al. [48] highlighted that an increase in fiber intake may actually worsen the symptoms of chronic constipation by increasing fermentation in the gut causing bloating. The latest NICE guidelines recommend that patients with IBS-C reduce their intake of insoluble fiber (i.e., wheat bran) and increase the proportion of soluble fiber, i.e., oats [49]. There is minimal evidence to suggest that increasing fluid intake will increase transit times unless an individual is dehydrated, but fluid intake of 1.5 L/day is usually advised. One controlled trial has shown that higher fluid intake in the presence of a high-fiber diet can improve symptoms of chronic constipation [50].

It is unclear whether exercise is beneficial in treating constipation [51]. One small RCT reported that regular exercise decreases constipation as per Rome I criteria [52], whereas another study did not show any benefit [53]. However, exercise is to be encouraged if only for its other proven health benefits.

In addition, position when defecating is important and, in many societies, squatting is the normal posture used. The sitting position with a 90° posture is a relatively recent innovation used in Western toilets. This sitting position causes a narrow anorectal angle that increases straining needed to empty the rectum. A study designed to compare the straining forces applied when sitting or squatting looked at normal volunteers defecating in three positions: sitting on a standard-sized toilet seat (41–42 cm high), sitting on a lower toilet seat (31–32 cm high), and squatting [54]. Both the net time needed for sensation of satisfactory bowel emptying and the degree of straining were significantly less in the squatting position compared with both sitting positions ($p < 0.0001$). Thus, patients are advised to adopt a position where the knees are above the hips with feet flat on the floor. There are now several devices available to enable a squatting position to be adopted on a pedestal toilet.

Laxatives

A variety of laxatives are now available for treating constipation; all are more effective than placebo

[55]. The mechanism of each type of laxative will help to determine the most appropriate type of laxative for the patient's symptoms (Table 63.5) [56].

Bulk Laxatives/Fiber

Undigestible fiber is an important part of our diet to provide stool bulk. Bulk-forming laxatives attract water, forming larger and softer stool, which in turn causes colonic distension, stimulating peristalsis and effective propulsion of stool along the colon to rectum. It is useful to those patients passing small hard stools. It may cause symptoms of bloating but is usually well tolerated. Systematic review has reported that bulking agents induce an average increase of 1.4 bowel movements per week [57].

Osmotic Laxatives

Osmotic laxatives increase the amount of water in the colon. Lactulose (semisynthetic disaccharide, poorly absorbed sugar), macrogols (inert polymers of ethylene glycol), or magnesium salts retain fluid in the colonic lumen causing osmotic diarrhea. Absorption of magnesium is limited but caution must be exercised in patients with impaired renal function [58]. Lactulose is less effective than macrogols [59] and its use may be limited due to flatulence and bloating caused by bacterial fermentation. Phosphate enemas are also an osmotic laxative.

Table 63.4 MRI-Based Classification for Obstructive Defecation Syndrome

Grade	Category	MR features	Management
1	Simple functional	Puborectalis dyssynergia	Pelvic floor rehabilitation
		EAS dyssynergia	
2	Grade 1 + minor anatomical defect	Rectocele ≤ 2 cm	Pelvic floor rehabilitation
		First-degree intussusception	
		Mucosal prolapse	
		Focal LA defect < 1 cm	
3	Grade 2 + major anatomical defect of posterior compartment	Rectocele > 2 cm or trapping	Surgical (colorectal)
		2nd-/3rd-/4th-degree intussusception	
		Rectal floor descent > 5 cm below PCL	
		Focal LA defect < 1 cm	
4	Grade 3 + major anatomical defect in all three compartments	Multiple pelvic organ prolapse	Surgical (urogynecology)
		Multifocal LA defects > 1 cm	
		Detachment of endopelvic fascia	
5	Surgical failure	Anastomotic stricture/deformity	Multidisciplinary approach
		Reduced rectal capacity	
		Rectal pockets, sinus tract, granuloma	
		Persistent rectocele, intussusception	
		Difficult emptying/contrast retention	
		Distortion of vaginal shape	
		Pudendal nerve neuropathy

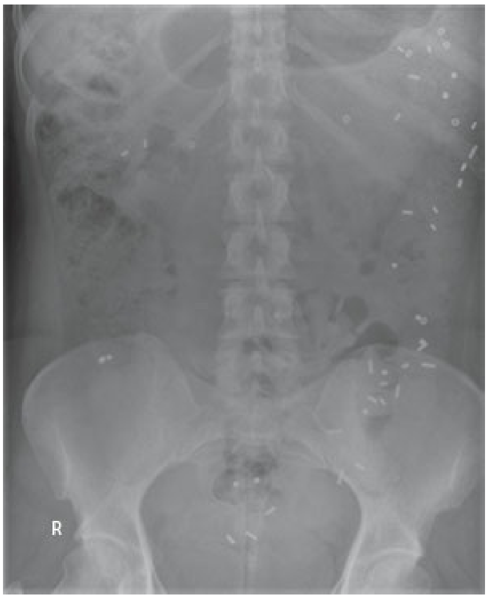

Figure 63.5 Shapes study of a patient with slow transit constipation taken at 120 hours. (Courtesy of Dr. Peter Guest, Consultant Radiologist, UHB, Birmingham, U.K.)

Stool Softeners

Stool softeners can be administered orally (liquid paraffin and docusate sodium) or rectally (arachis [peanut] oil and glycerol) to soften and lubricate the stool.

Stimulant Laxatives

Diphenylmethane derivatives such as bisacodyl, sodium picosulphate and anthraquinone derivatives such as senna are stimulant laxatives, which act on the enteric nervous system to increase intestinal motility but may cause abdominal cramps as a consequence. This can be managed by titrating the dose. Long-term use of anthraquinone-derived stimulants can generate brown discoloration of mucosa known as pseudomelanosis coli. Docusate sodium and glycerol are both stimulants and softening agents.

Parasympathomimetics such as neostigmine enhance parasympathetic activity in the gut and increase intestinal activity. It is rarely used for constipation. Neostigmine can be used in selected cases for the treatment of pseudoobstruction that has failed to settle with conservative management [60].

5-HT4 Receptor Agonists

Prucalopride is a selective serotonin (5-HT4) receptor agonist with prokinetic activity. NICE has recommended the use of prucalopride in women with chronic constipation who have failed to improve with at least two laxatives from different classes at the highest recommended dose for at least 6 months [61]. Efficacy of the treatment should be reviewed after a 4-week trial of the medication. In elderly patients, a reduced dose of 1 mg/day is recommended. The pivotal randomized double-blinded placebo-controlled trials carried out with a total of 1999 adults with chronic constipation (PRU-INT-6, PRU-USA-11, PRU-USA-13) showed that the proportion of subjects treated with prucalopride 2 mg/day who had three or more spontaneous complete bowel movements per week during weeks 1–4 ranged from 23.7% to 32.1%, compared with 9.8% to 11.5% for placebo (all $p \leq 0.001$) and during weeks 1–12 ranged from 19.5% to 28.9%, compared with 9.6% to 13.0% for placebo (all $p \leq 0.001$) [62–64]. Headache, nausea, and diarrhea were more common side effects with prucalopride compared to placebo [55]. A smaller study comparing efficacy of prucalopride on patients with different subtypes of constipation showed that all categories of constipation may respond to prucalopride [65].

Table 63.5 Summary of Laxatives

Laxative type	Examples of laxatives	Mechanism of action	Side effects
Bulk forming	Ispaghula husk,	Increase fecal mass	Bloating

	methylcellulose		
Osmotic	Lactulose, macrogols, magnesium salts	Increase water in colon	Flatulence, bloating Dehydration Electrolyte abnormality
Stool softeners	Liquid paraffin, docusate sodium	Luminal water binding, increases stool bulk	Abdominal pain and cramps
Stimulant	Bisacodyl, sodium picosulphate, senna	Increase intestinal motility	Abdominal pain and cramps
5-HT4 agonists	Prucalopride	Stimulates colonic and intestinal peristalsis	Nausea, vomiting, abdominal pain, dyspepsia, flatulence, headache
Colonic secretagogues	Linaclotide	Promoted fluid secretion into GI lumen	Diarrhea
Colonic secretagogues	Lubiprostone	Promoted fluid secretion into GI lumen	Nausea, vomiting, abdominal pain, dyspepsia, flatulence, headache

Source: Tack J et al., *Neurogastroenterol Motil*, 23(8), 697, 2011.

Colonic Secretagogues

Lubiprostone is a member of a new class of medication called prostones, which activate type 2 chloride channels (CIC-2) on enterocytes, and promote the secretion of chloride-rich intestinal fluid without altering the serum concentration of sodium or potassium. It is thought that by increasing the intestinal secretions, small bowel motility is increased, thereby increasing the passage of stool [66–68]. Three RCTs comparing lubiprostone 24 μg twice daily with placebo in 610 patients showed that lubiprostone significantly enhanced bowel movement frequency and relieved other constipation-related symptoms [68–70]. The most commonly reported side effects include nausea and diarrhea [55]. It is currently licensed for treatment of chronic idiopathic constipation. There are limited but supportive data on safety and efficacy of use of lubiprostone in the elderly population [71], constipated patients with Parkinson's disease [72], and treatment of opioid-induced constipation [73].

Treatment of Irritable Bowel Syndrome with Constipation

It is important to identify symptoms that are affecting the individual patient and tailor the treatment accordingly [10,49]. To treat their constipation, bulk-forming laxative, such as soluble fiber (ispaghula husk or oats), or osmotic laxatives (macrogol) are recommended. Antispasmodics or low-dose tricyclic antidepressants may ease abdominal pain associated with IBS.

Linaclotide is currently licensed for the treatment of moderate to severe IBS associated with constipation. It is a first-in-class, oral guanylate cyclase-C receptor agonist of enterocytes. It induces intestinal chloride and fluid secretion through cyclic GMP production [74]. Three RCTs comparing linaclotide with placebo containing 1582 patients showed that 290 μg once daily significantly improved abdominal pain, bloating, and constipation associated with IBS-C [75–77]. The most frequently reported side effect was diarrhea [78,79].

Biofeedback

Biofeedback is based on behavior modification and operant conditioning [80]. It teaches patients how to control a physiological function that is not usually under conscious control by using an instrument that provides visual and/or auditory feedback of an action. This therapy has been reported to be effective in both constipation and incontinence [81]. Three main methods of monitoring defecation and providing biofeedback to patients are EMG biofeedback, manometric biofeedback, and balloon sensory training [82]. None have been shown to be consistently more effective than any other method [83] but EMG biofeedback is the method most widely used [84].

Gut-directed biofeedback involves patients being taught to defecate successfully using bracing of the abdominal wall muscles and effective relaxation of the pelvic floor muscles [85]. This may be enhanced by use of a water-filled rectal balloon, which patients attempt to expel [86]. Patients are enabled to recognize the sensations associated with relaxation of the pelvic floor and anus together with correct use of abdominal muscles to create an effective pushing force and thus learn to defecate effectively. Patients may also be given basic instruction on gut anatomy and function to enhance their understanding, as well as behavioral advice about frequency and length of toilet visits, posture on the toilet, and dietary habits [87].

Numerous nonrandomized studies of biofeedback for idiopathic constipation have published positive results, suggesting that biofeedback is an effective intervention for constipation due to both slow gut transit [82,88] and evacuation disorders [89–92]. Biofeedback has been shown to be more effective than laxatives [93], relaxation training [89], and placebo [90]. A systematic review of seven trials, with a total of 413 participants, concluded that biofeedback conferred a sixfold increase in the odds of treatment success [84].

There is some evidence that evacuating regularly may also stimulate gut transit and so improve symptoms [86]. Whereas short-term results may vary from 60% to 90% improvement [94], long-term studies report sustained improvement in around 50% of patients [95]. As the treatment involves dedicated sessions with a single clinician, the development of that therapeutic relationship may also contribute to improvements in quality of life.

Psychological Therapy

Psychological therapies can improve symptoms without interacting with pharmacological treatments [96]. Additionally, they can improve patient's ability to cope with the symptoms thus improving quality of life. Discussion of symptoms with a supportive health-care professional who listens and responds appropriately can reduce feelings of isolation and shame. Some patients need more formalized psychological interventions, including counseling and cognitive behavioral therapy.

Rectal Irrigation

Rectal irrigation was originally used in clinical practice for children with spina bifida [97]. Indications were extended to adults with neurogenic bowel dysfunction after conservative management had failed [98]. It is now used in a wider variety of conditions such as rectocele, obstructed defecation, and other functional bowel problems [99]. It is taught to patients as a self-management method. Several products are available on the market; hence, the product can be chosen to suit individual patient's needs. They are designed to be used while sitting on the toilet to avoid accidents when transferring. Mini systems allow irrigation with up to 90 mL of water (Aquaflush Compact, Mini Qufora) and are used to aid initiation and completion of defecation, being helpful in patients with symptoms of ODS and incomplete evacuation [100,101]. The larger systems allow irrigation with a cone or balloon catheter, enabling instillation of larger quantities of water, used in patients with slow transit constipation or neurological abnormalities (Aquaflush Quick, Qufora, Peristeen).

In long-term follow-up of 169 patients over 56 months, rectal irrigation was found to be effective in 44% of patients with fecal incontinence and 62% of patients with defecatory disorders [24]. Collins and Norton retrospectively assessed 50 consecutive patients using the mini system and found that 62% improved or their symptoms completely resolved [102]. Absolute contraindications include stenosis, colorectal cancers, acute diverticulitis, and active inflammatory bowel disease. Most complications reported are minor and include abdominal cramps, minor anal bleeding, and leakage of irrigant after completion [99]. Introduction of a medical device and administration of water carry a risk of bowel perforation. In a consensus review of best practice, the perforation risk was estimated at 1 per 50,000 and was thought to be noncumulative [103]. For this reason, it is important that irrigation is taught by qualified experienced clinicians. Faaborg et al. have studied the long-term effects of using rectal irrigation in patients with functional bowel disorders and found that there was no long-term deterioration in anal sphincter function or rectal compliance [104].

Neuromodulation

PTNS

Percutaneous tibial nerve stimulation (PTNS) delivers electrical stimulation through an acupuncture needle placed medially above the ankle. It is postulated that stimulation of the tibial nerve in turn stimulates the sacral nerves thus neuromodulating bowel motility and/or sphincter function. The treatment is outpatient based and consists of 12 weekly 30 minute sessions. In a pilot study of 18 patients with constipation, the Wexner constipation and Patient Assessment of Constipation Quality of Life scores were significantly improved after a course of 12 treatments. Stool frequency also increased with a decrease in laxative use, although these results were not statistically significant [105].

SNS

There is growing interest in considering sacral nerve stimulation (SNS) as a first-line surgical intervention for constipation after incidental finding of increased bowel frequency and improvement in constipation of those who underwent permanent SNS for bladder dysfunction or fecal incontinence [106–111]. The latest review on the efficacy of SNS for constipation management in 225 temporary neuromodulations and 125 permanent implants showed more than 50% had objective evidence of improvement on bowel diaries on temporary neuromodulations and were maintained in approximately 90% of patients who subsequently underwent permanent implantation over medium-/long-term follow-up [112]. Subanalysis of the European trial data demonstrated improvement in both colonic transit and ability to evacuate as well as improvement in quality of life [113]. Improvement in defecatory frequency with temporary wire placement has been suggested as a good predictor of successful outcome with a permanent implant [108,112,113].

Complementary Medicine

Many patients resort to alternative medicine in desperation to find a solution to their symptoms. A small study of 30 patients with STC found that acupuncture leads to a decrease in the use of laxatives and improvement in symptoms [114]. There are no other robust studies available on the role of complementary therapies. Patients should be advised to exercise caution when considering other interventions.

SURGICAL MANAGEMENT

Surgery has a role in the management of carefully selected patients with chronic constipation who fail to improve with current conservative management [109–111].

Antegrade Continence Enema [50]

Antegrade continence enema (ACE) is considered as an alternative to colostomy in select patients with constipation or fecal incontinence. ACE surgery requires a continent connection to be created between the abdominal wall and cecum. Malone et al. [115] described the use of reversed appendix to maintain continence, which can now be performed laparoscopically assisted. If a patient has had previous appendicectomy or has an atrophic appendix, tubularized ileal or cecal conduits are used. Patients are taught to intubate the ACE with a catheter and perform antegrade colonic enema with irrigant, usually a mixture of water and phosphate enema. In general, success rates have been lower in adults than in children [110], but a Danish group has reported a favorable outcome in 69 adults who underwent ACE procedure with mean follow-up of 75 months [116].

Long-term complications include stoma stenosis, leakage, or failure to effectively treat the original symptoms requiring revision, reversal, or conversion to a stoma [7]. It is worth considering combining the ACE procedure with a colostomy in disabled patients and patients with persistent left colonic inertia despite retrograde irrigation [117].

Defunctioning Stoma

A stoma may be formed as definitive procedure, as guide to further treatment, or as salvage from failed alternative interventions [110]. In patients with slow transit constipation who have failed maximal conservative management, defunctioning ileostomy may be formed as a guide to colectomy [51]. Colectomy can be avoided in patients who have unsatisfactory ileostomy function or persistent abdominal symptoms such as pain or bloating.

Colectomy

Colectomy should only be considered as a treatment option for patients with diffuse slow colonic transit but normal gastric and small bowel transit [110]. Once a decision to resect has been made, then the next consideration is how much to resect. Two studies have reported good results by performing segmental resections or subtotal colectomies based on segmental transit time measurements [42,118]. However, limited subtotal colectomy with cecorectal or ileosigmoid anastomosis is generally reported as having an inferior functional outcome to ileorectal anastomosis [106]. The long-term results of surgery for slow transit constipation may be poor. However, a good outcome can be predicted in patients with slow transit constipation without impaired evacuation and overt psychological or psychiatric disease [119].

Surgical Treatment Options for Obstructive Defecation

Surgical repair of anatomical deformities identified in patients with ODSs should only be carried in those who have exhausted all conservative treatments. The aim of surgery is to correct anatomy with a relief of associated symptoms [120], although correction of anatomical abnormalities alone does not always lead to restoration of normal function [121]. To decide on the best treatment options, understanding the pelvic floor anatomy and the DeLancey level of pelvic organ support (Table 63.6) will help [122].

Rectocele

Surgical repair of rectoceles in patients presenting to the colorectal surgeon is usually recommended when they are 2 cm or more in depth with the need for patient to digitate to defecate and with evidence of significant trapping on defecating proctogram or MRI proctogram [123] via transvaginal, transperineal, transanal, or abdominal approaches. Transvaginal posterior colporrhaphy was found to have the lowest rate of recurrence of rectocele/enterocele in a Cochrane Review of all rectocele repairs [124]. Dyspareunia has been reported in up to 25% of women following posterior colporrhaphy. A systematic review of the use of biological materials in urogynecological surgery has shown that there was no additional benefit to the use of biological material in rectocele repair [125].

Stapled transanal rectal resection (STARR) involves resections of internally prolapsed rectum circumferentially using a circular stapling device. Jayne et al. reported 1-year outcome of patients who underwent STARR procedure for evacuation disorder on the European STARR registry. This showed significant improvement in symptom severity and quality of life score. However, 36% experienced complications including urgency, pain, urinary retention, bleeding, and septic events [126]. A consensus panel has developed a treatment algorithm for offering STARR by experienced surgeons for patients with evacuation disorder with a rectocele and/or intussusception [127].

Enterocele/Sigmoidocele

Enterocele or sigmoidocele occurs as a result of herniation of small bowel (enterocele) or sigmoid colon (sigmoidocele) through the uterosacral ligament at the vaginal apex into the pouch of Douglas, leading to separation of the rectovaginal septum. This can impede defecation leading to pelvic discomfort and perineal pressure with straining [128]. There are some physiological enteroceles, but if an enterocele or sigmoidocele impairs rectal emptying on defecating proctogram, then it is likely to be contributing to the patient's symptoms of ODS. Enteroceles can be repaired transabdominally laparoscopically (ventral mesh rectopexy and sacrocolpopexy) or vaginally in conjunction with pelvic floor repair (Table 63.6).

Table 63.6 DeLancey Level of Pelvic Organ Support

	Support	**Defect**
Level 1	Superior suspension of the vagina to the cardinal–uterosacral complex	Enterocele/sigmoidocele
Level 2	Lateral attachment of the upper two-thirds of the vagina	Rectocele
	Rectovaginal septum supporting posterior vaginal wall	Rectal intussusception
Level 3	Distal fusion of vagina into the urogenital diaphragm and perineal body	Supra-anal rectocele

Source: DeLancey JO, *Am J Obstet Gynecol*, 166(6 Pt 1), 1717, discussion 24–28, 1992.

Internal Intussusception/Rectal Prolapse

Surgically, the rectum is mobilized and returned to its correct anatomical position within the pelvis and many techniques have been described [120]. In suture rectopexy, the rectum is fully mobilized and sutured to the presacral fascia. In patients with redundant loop of sigmoid with preoperative symptoms of constipation, sigmoid resection may be considered. Laparoscopic resection rectopexy (Frykman–Goldberg procedure) has been shown to be safe with good long-term outcome [129,130]. The use of mesh has been introduced on assumption that a foreign body will produce stronger adhesions and fibrosis than dissection and suture alone. Various techniques have been described, including anterior sling rectopexy (Ripstein procedure), posterior mesh rectopexy (Well's posterior rectopexy), and use of fascia lata to fix the sacral promontory (Orr–Loygue procedure) with further modifications using different types of mesh. Systematic review on ventral rectopexy for rectal prolapse and intussusception showed that there appears to be a reduction in postoperative constipation if posterior rectal mobilization is not performed with division of lateral ligaments [131]. Current literature has shown modern nerve-sparing laparoscopic ventral mesh rectopexy that showed over 50% improvement in the short and medium term [132,133]. Robotic-assisted rectopexy has the advantages of 3D vision, a better view to identify and spare parasympathetic innervation to the rectum, and having flexible tips of instruments for suturing over laparoscopic approach. Recent literature supports safety and feasibility of robotic-assisted rectopexy [134]. There is limited evidence of the best mesh to be used. An expert panel (grade C evidence) has recommended the use of biological mesh in young women of reproductive age, diabetics, smokers, patients with history of pelvic radiation or IBD, or intraoperative breach of rectum or vagina [133].

Perineal procedures are considered in patients with full-thickness rectal prolapse who may not be fit for an abdominal procedure and may carry a higher recurrence rate [135]. Delorme's procedure involves transanal mucosal stripping with plication of the muscular wall of the rectum. The Altemeier procedure is transperineal resection of the rectosigmoid, which can be offered to frail patients with symptomatic large prolapse.

CONCLUSION

The management of constipation can be challenging. The majority of the patients can be managed conservatively with a multidisciplinary approach (see Chapter 65) in complex patients. Patients with idiopathic constipation can be managed conservatively without recourse to major surgical interventions. Surgery carries risks of serious morbidity and patient selection for surgical intervention must be carried out with caution. For a few, surgery can offer effective treatment with improvement in function and quality of life.

64 Female Sexual Dysfunction

Seth D. Cohen and Irwin Goldstein

The objective of this chapter is to provide relevant evidence-based clinical information to help practitioners diagnose and treat specific biological-based sexual health pathophysiologies in women.

Female sexual dysfunction (FSD) is recognized as a common medical problem in all age groups. Data from the National Health and Social Life Survey, a study that describes both the distribution of sexual practices and the changes in these practices under current conditions, found that sexual dysfunction is more prevalent in women (43%) than in men (31%) [1]. Shifren et al. [2] evaluated data from the population-based Prevalence of Female Sexual Problems Associated with Distress and Determinants of Treatment Seeking study. This study estimated the prevalence of sexual problems and sexually related personal distress in U.S. women in addition to the prevalence of sexual disorders of desire, arousal, and orgasm. They concluded that about 40% of those with a sexual disorder of desire, arousal, or orgasm have concurrent depression. In 2014, there were over 25 FDA-approved drugs for men's sexual health; despite the significant number of women with bothersome FSD, there was only one drug that was FDA approved in women. This drug, ospemifene, is licensed to treat moderate to severe dyspareunia in menopausal women [3]. We feel that it is of vital importance to address female sexual problems systematically and will take you step-by-step through the presentation, diagnosis, and treatment of many FSD disorders in an organized and complete fashion.

A basic understanding of what sexual dysfunction means is a key for any clinician seeing FSD in their office. Based on the most current version of the DSM-V [4], sexual dysfunction is a heterogeneous group of disorders that are characterized by a clinically significant disruption in a person's ability to respond sexually or to experience sexual pleasure. In this, the recognized FSD disorders are female orgasmic disorder, female sexual interest/arousal disorder, and genitopelvic pain/penetration disorder.

To provide the best care to women struggling with FSD, clinicians must understand that sexual problems are commonly associated with significant personal distress including a diminution of self-worth and self-esteem, a reduction in life satisfaction, and a decline in the quality of the relationship with her partner [5]. Thus, to provide the best overall care for these patients, it is important for clinicians to be familiar with the basic aspects of appropriate women's sexual health-care delivery. "Sexual health" refers to a state of physical, emotional, mental, and social well-being related to sexuality [6]. Women have the right to a positive and respectful sexual relationship and to have pleasurable and safe sexual experiences, free of coercion, discrimination, and violence. Women have the right to sexual equity, the freedom from all forms of discrimination and violence. For sexual health to be arraigned and maintained, the sexual rights of all women must be respected, protected, and fulfilled [7].

To properly assess women with sexual dysfunction, it is necessary to take a biopsychosocial approach. To engage this method of diagnosis and treatment, a clinician may need to utilize multiple different health-care professionals from various fields in order to get to the root of the sexual dysfunction. This multidisciplinary methodology (Figure 64.1) has allowed us to have great success in diagnosis and treatment of difficult presentations of FSD.

VILLAGE

Despite the fact that female urology and urogynecology practitioners have a unique position to understand the anatomy and physiology of the peripheral genitalia and pelvic floor constituents, sexual medicine issues are usually highly complex and are, in general, secondary to interrelated psychological, physiological, and relationship issues molded with distinct couple dynamics. In most cases, women with sexual health concerns should consider undergoing concomitant psychological and physical therapy assessment and management by an appropriately trained specialist [7].

Traditional management of a woman with sexual health problems usually involves evaluation by a single provider with expertise in a specific discipline (i.e., medicine, psychotherapy, or physical therapy). Based on the outcome/initial diagnosis, the patient may be referred to a provider(s) in a different discipline(s). There are limitations to this traditional model: Sexual health is more than just the absence of symptoms. Expertise of the provider is often constrained by training and exposure as well as access to care by providers in different disciplines. There may be pelvic floor, psychological, or biological issues not addressed by this traditional model. Thus, at our institution, we have introduced a novel health-care technique that is able to assess these complicated issues in one patient visit; we call it the village health-care technique where multiple providers from various different backgrounds are able to take care of a single patient with complex disorders. We recognize that no one medical professional can take care of all sexual problems by himself or herself. This technique employs multiple different health-care specialists all of whom treat sexual dysfunction but whose expertise and training are unique to their specialty. In our office, a typical patient will be evaluated by a registered pelvic floor physical therapist, a sex therapist/sexuality educator, and a sexual medicine physician. If it is possible to recreate this office scenario in other offices, we feel that it has the highest yield for the proper diagnosis and treatment for FSD patients.

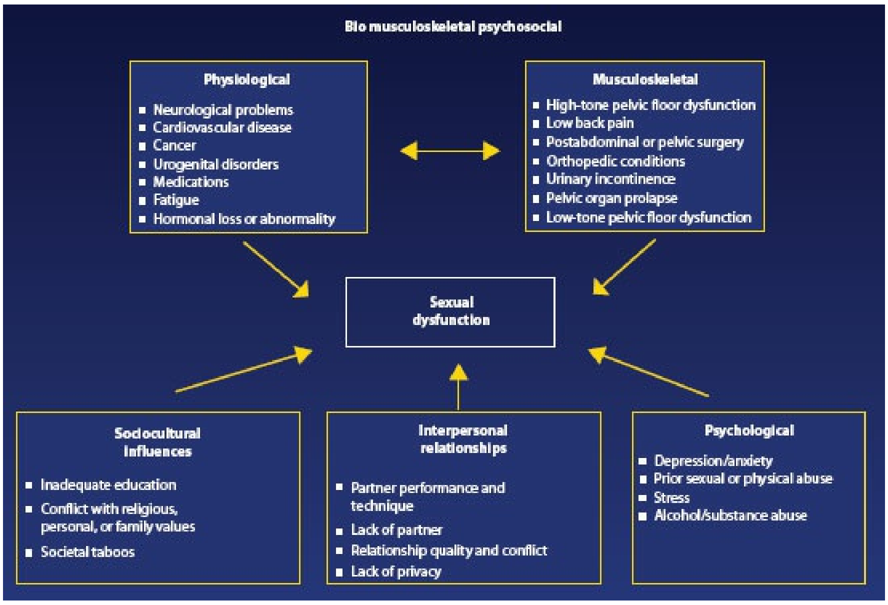

Figure 64.1 Stepwise, multidisciplinary approach to addressing female sexual dysfunction.

Psychosocial Assessment/History

It is not necessary to do an exhaustive sexual and family history for most evaluations. The patient’s description will indicate whether she experiences the dysfunction at all times or only under certain circumstances [8]. Identification of a precipitating factor will likely reveal a pattern within the mindset or experience of the patient, which would help explain the shift in sexual function, and it is helpful to establish if the change was preceded by or concurrent with major life stressor (breakup, death in the family, job problem, newborn in the house). In long-standing cases of primary dysfunction, it is more important to look for a precipitating cause with an emphasis on what is currently maintaining the dysfunction. For instance, if there was a traumatic or painful first sexual experience, is the woman still afraid that sex will hurt? Is fear or anxiety leading to painful pelvic floor muscle contractions during attempts at coitus?

The health-care provider should briefly screen all patients for obvious psychopathology that would impact the treatment algorithm for FSD. The health-care provider should investigate if the psychiatric symptoms are currently present or have been treated previously. These symptoms may be interrelated with the sexual disorder. This will help guide the clinician in defining goals and boundaries for the patient. Psychological factors [9] that can easily interplay with FSD include previous sexual trauma and abuse [10], depression [11], psychoses, anxiety, distraction, sexual neurosis, sexual inhibitions, and/or interpersonal relationship issues.

There is a statistically significant increase in depression for females with FSD. If the patient is depressed, then the severity of the depression should be clarified and documented accordingly. Furthermore, all patients who experience major depression should be questioned about suicide risk [11]. Thus, a close working relationship between the FSD clinician and sex therapist is typically warranted in cases of major/severe depressive symptoms.

Pelvic Floor Assessment in Women's Sexual Function

Overview

Normal function of the pelvic floor musculature is essential in maintaining appropriate sexual function. Both "low-tone pelvic floor dysfunction" and "high-tone pelvic floor muscle dysfunction" can be closely associated with women's sexual health concerns. Hypotonus of the pelvic floor muscles, secondary to childbirth, trauma, and/or aging, is related to urinary incontinence during orgasm, vaginal laxity, and/or thrusting dyspareunia secondary to pelvic organ prolapse. Hypertonus of the pelvic floor secondary to childbirth, postural stressors, microtrauma, infection, adhesions, and surgical trauma can contribute to symptoms of urinary retention, reduced force of stream, dysuria, urgency, penetrative dyspareunia, and/or vaginismus.

Assessment

The assessment of pelvic floor tone is determined by the woman's ability to isolate, contract, and relax the pelvic floor muscles. The pelvic examination should begin with a digital exam, which is performed by exerting light pressure on the lateral walls of the vagina to assess whether the woman can squeeze on the examining finger and elevate the pelvic floor without simultaneously contracting the abdominal, gluteal, or adductor muscle groups. If the patient is not able to produce sufficient muscle strength to compress the finger or is not able to sustain that pressure for several seconds, she may be exhibiting a low-tone pelvic floor dysfunction pattern. If, conversely, the woman experiences muscle tenderness or pain when pressure is applied to the lateral vaginal wall or during an attempted squeeze against resistance, she may be exhibiting a high-tone pelvic floor dysfunction pattern. A perineometer or an electromyography probe, designed to measure muscle activity, can verify these physical examination findings [12–15].

Hypoactive Pelvic Floor

Weakness and laxity of the pelvic floor muscles represent a spectrum of symptoms and conditions that include women with pelvic organ prolapse with or without urinary or fecal incontinence. Risk factors include age, heredity, trauma, menopausal status, and chronic medical conditions such as chronic obstructive pulmonary disease, obesity, and constipation. Stress incontinence that occurs with increased intra-abdominal pressure and maneuvers such as sneezing, coughing, and straining is related to abnormalities in urethral closure pressure and poor pelvic muscle support. Sexuality will often be adversely affected by a hypoactive pelvic floor since severe incontinence and prolapse symptoms are a source of anxiety and interfere with the overall sexual satisfaction experience. These women often express concern about feeling undesirable and fearing embarrassment [14–17].

Hypersensitive Pelvic Floor

Hypertonus of the pelvic floor musculature accounts for some of the concerns of female patients who present for evaluation of sexual health concerns. Hypersensitivity disorders involving the genitourinary tract represent a spectrum of symptoms and conditions that include chronic bacterial cystitis, urinary urgency and frequency, urethral syndrome, interstitial cystitis, vulvar pain, and perineal and pelvic pain. Sexuality is adversely affected for the majority of women with hypersensitivity disorders of the bladder, bowel, and vulva and high-tone pelvic floor dysfunction. Patients who can tolerate coitus often suffer a flare of their symptoms for days as a result of sexual activity, which then becomes a negative reinforcement for future sexual activity [14–17].

Physical Therapy Treatment

Although treatment regimens for high and low pelvic floor tone with resultant sexual dysfunction need a separate chapter, we will go over a few important tools that physical therapists use to treat the aforementioned disorders. Burning, stinging, irritating, raw, tearing, and searing pains are the most common complaints reported during and after vaginal penetration. If these symptoms are felt at the vaginal introitus and superficial structures such as the vulva, perineal body, posterior fourchette, and episiotomy site, then most likely the superficial muscle layers of the pelvic floor are implicated. If deeper vaginal pain occurs, restriction of the vaginal canal, levator ani and obturator internus muscle trigger points, or sacroiliac, symphysis pubis, hip, or lumbosacral joint dysfunction may be implicated [14].

Disorders of the female pelvic floor that result in bladder/urethra dysfunction and/or sexual dysfunction are common. Conservative therapies for hypersensitivity disorders of the pelvic floor are aimed at muscle reeducation. An individualized pelvic floor rehabilitation program aimed at facilitating sexual comfort and pleasure for patients can be designed. Massage of the pelvic floor can be performed to elongate shortened muscles and decrease high-tone spasm in such patients. Conservative therapies for low-tone pelvic floor dysfunction are also aimed at muscle reeducation. Pelvic floor muscle strengthening exercises, augmented with biofeedback and/or electrical stimulation to the pelvic floor, can be initiated [12,14,15].

Once the musculoskeletal diagnosis for vaginismus and dyspareunia has been established, treatment should include the following steps [8]:

1. Correct any joint malalignment to promote pain-free joint mobility.
2. Teach the patient self-correction joint techniques.
3. Inform about positions for sexual intimacy.
4. Eliminate tender trigger points in all of the muscles.
5. Eliminate or reduce scar adhesions and tissue restrictions.
6. Teach pelvic floor muscle awareness with a biofeedback device.
7. Reeducate the pelvic floor muscles to be relaxed upon penetration.
8. Stretch the muscles surrounding the vagina by combining down training with dilators.
9. Correct muscle imbalances by down training (relaxation) and up training (strengthening).
10. Correct muscle imbalances by teaching correct muscle timing and recruitment.
11. Educate about lubricants.

Sexual Health-Care Provider Assessment

Clinical History

There is limited consensus on management paradigms for the diagnosis of women with sexual health complaints. As it concerns the biological-based sexual dysfunction, the most relevant aspect of the diagnosis is the history and physical examination.

Clinical history taking centers on three components: sexual, medical, and psychosocial aspects. The sexual history should begin with the patient describing the sexual problem. The following questions may be utilized to help obtain maximal descriptive information. These are based on women presenting with sexual dysfunction rather than those presenting with combined incontinence problems, where the questions may be used as a modified basis to open discussions.

1. Do you ever experience problems with sexual interest, sexual arousal, and/or sexual orgasm?
2. Sexual problems are common in women who have urinary complaints. Do you have any urinary issues that bother you like frequency, urgency, or stress incontinence?
3. What is your current sexual function in terms of interest, arousal, and orgasm compared to when you were at your peak sexual function?
4. How long have you had the sexual problem? Timing? Frequency during the day, month, or year?
5. Does the sexual problem occur only during partner-related sexual activity or during manual manipulation?
6. In which situations is the sexual problem minimized? Maximized?
7. Is the sexual problem associated with any degree of discomfort, tenderness, soreness, or pain? If so, can you localize the site of pain in a schematic diagram of a woman’s genitalia?
8. What tests/evaluations have you already had in regard to your sexual health concern?

The medical history should include focused questions on any accompanying medical/surgical illnesses and/or the use of medications [16]. Urogynecologic history taking such as incontinence [17–20], frequent urinary tract infections, interstitial cystitis [21], pelvic surgeries, childbirth [22,23], abortions, episiotomy, sexually transmitted diseases [24], pelvic inflammatory disorder, endometriosis, fibroids [25], hysterectomy with or without oophorectomy, and menopausal status [26] should all be obtained.

Topics of importance in the medical history should include a cursory history of the use of various birth controls the patient has taken and the timing of the sexual dysfunction in relation to starting and stopping them and neurological diseases like a spinal cord injury or trauma to the pudendal nerve and its branches. Chronic diseases like diabetes, anemia, hyperlipidemia, coronary artery disease should also be addressed including medications taken for these chronic illnesses. A history of holistic and integrative medications and vitamin supplementation is warranted to better understand the extent to which the severity of the illness has driven the patient to such ailments. Over-the-counter and illicit drug use like cocaine, marijuana, and ecstasy should be addressed in the history.

Since the endocrine system, including the sex steroids, plays a pivotal role in genital function, a complete evaluation of the endocrine function is warranted. We check nine lab values for all women who present to our institute with sexual dysfunction: estradiol [27,32], progesterone, testosterone [28–30] and calculated free testosterone, prolactin, sex hormone–binding globulin (SHBG), thyroid-stimulating hormone (TSH) [31], luteinizing hormone, follicle-stimulating hormone (FSH), and dihydrotestosterone (DHT). Along with the hormone evaluation, the medical history should routinely probe and evaluate for estrogen deficiency [32,33] such as vaginal dryness, vaginal bleeding with minimal vaginal manipulation, hot flashes and night sweats, and other symptoms of menopause. Symptoms of androgen insufficiency (i.e., menopause or a girl taking birth control pills) would include fatigue, lack of energy, diminished skeletal muscle mass and strength, depressed mood, lethargy, insomnia, hypersomnia, and lack of interest in sexual activity [34–36].

It is relevant to inquire about the sexual heath of the patient’s partner. For women in a relationship with men, male sexual dysfunction such as erectile dysfunction, early ejaculation, or an anatomical concern such as Peyronie’s disease may exist and need to be addressed by a urologist.

Finally, an important caveat to history taking in women with sexual health concerns is that history taking may be viewed in some women as actually the beginning of their treatment. Women are often empowered following a detailed discussion about their sexual health concerns. Women who have undergone a detailed medical background interview have initiated the first step in overcoming past failures to take action in this area. It is not uncommon for the discussion with the health-care clinician to expose a breadth of important information that will be vital in the overall treatment plan.

Validated Questionnaires

Validated, reliable, standardized self-rated questionnaires [32–35] are useful to assist in identification of the presence or absence of the various domains of women’s sexual dysfunction, such as sexual desire, sexual arousal, orgasm, and/or sexual pain. The most common of such questionnaire is the female sexual function index [36,37]. This self-reported patient screening tool is used to score symptoms against normative values for populations of women with and without sexual dysfunction. As in all areas of clinical medicine, the use of screening tools for clinical diagnosis has recognized limitations. The determination of particular psychological contributors or confounds, contextual conditions, and other features and characteristics that affect an individual women requires a more traditional assessment through structured history and physical examination.

Physical Examination

The physical examination for a woman with sexual health concerns should be tailored to the sexual medicine complaint obtained on history taking. For example, if during history taking genital itching is a major sexual health problem, a careful assessment would follow for the presence/absence of a genital dermatitis condition [38]. If a woman with sexual health problems is under the age of 50 and has sexual pain, a careful physical examination should evaluate for the presence of hormonally mediated vestibulodynia vs. neuroproliferative vestibulodynia [39,40]. Similar complaints of sexual pain in a woman over 50 years of age should assess for the presence of vaginal atrophy with dryness, loss of rugae, mucosal thinning, pale hue, and lack of shiny vaginal secretions; all are indications of menopausal hormonal status [32,33].

The physical examination should be performed ideally without menses and without intercourse or douching for 24 hours before the exam. If dysfunction occurs at a specific time, such as mid-cycle dyspareunia, the physical examination should be scheduled at the time of the sexual problem. The genital-focused examination should be considered routine in the diagnosis of women's sexual health problems, but its personal character demands that a rational explanation exist for its inclusion in the diagnostic process. A focused peripheral genital examination is recommended in women with sexual dysfunction for complaints of dyspareunia, genitopelvic pain/penetration disorder, genital arousal disorder and combined arousal disorder, orgasmic disorder, pelvic trauma history, and any dermatologic disease affecting genital health such as herpes or lichen sclerosis. The examiner may also assess for anal and vaginal tone, voluntary tightening of anus, and bulbocavernosus reflexes in women with suspected neurological disorders [41].

Patient consent to examination is particularly important. It is vital that the patient is aware of the purpose of the exam and understands that she has the final authority to terminate the physical examination, to ask questions, to have control over who is in attendance, and to understand the extent of the assessment. Inclusion of the sexual partner, with permission of the patient, is advantageous and provides needed patient support. Allowing the patient to observe any pathology via digital photography is often therapeutic, allowing, for the first time in many cases, an illustration and connection of a detected physical abnormality with the sexual health problem. If a genital sexual pain history exists, the patient should point with her finger to the location/s of the discomfort during the physical examination [34].

Independent of the gender of the examining health-care clinician, it is strongly recommended that a female chaperone the health-care clinician during the entirety of the examination. If a chaperone is declined then this should be documented contemporaneously, preferably with witnessing. The patient should wear a sheet to cover her lower torso. The patient should be placed in the lithotomy position and the examining health-care clinician should use vulvoscopy (Figure 64.2) with magnified vision and a focused light source [34]. In addition, warming the room creates a more relaxed environment in which the patient will feel more comfortable.

External Examination

The first part of the examination involves inspection of the vulva and labia majora. Two gloved fingers are placed on either side of the clitoral shaft, and using an upward force in the cephalic direction, the prepuce is retracted to gain full exposure of the glans clitoris, corona, and right and left frenulum emanating at 5:00 and 7:00 from the posterior portion of the glans clitoris (Figure 64.3a and b). The labia minora are inspected for labial resorption and for their ability to meet at the midline posterior fourchette (Figure 64.4a and b). The maximal labial width is recorded to compare pre- and posthormone supplementation. Inspection of the urethral meatus is performed (Figure 64.5a) and any erythema, stenosis, or meatal prolapse (Figure 64.5b) is noted. Using gauze to maximally retract the labia minora, the labial–hymenal junction (Hart's Line) is identified. The Q-tip cotton swab is placed at multiple locations on the vestibule, which is defined as the tissue medial to Hart's line (Figure 64.6). A Q-tip cotton swab test is performed, gently applying pressure on the minor vestibular glands (Figure 64.7a), documenting the quality (0–10 pain scale works well here) of the discomfort or pain or erythema (Figure 64.7b) in a clockwise fashion.

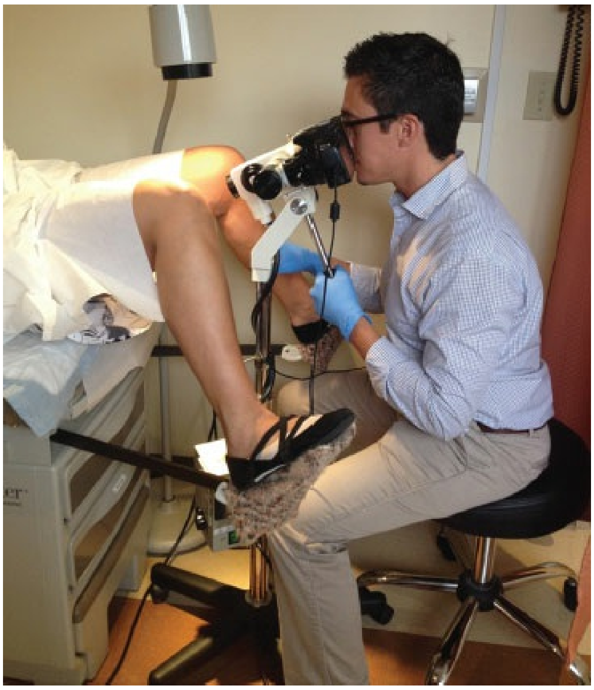

Figure 64.2 Vulvoscopy. The examining health-care clinician should use vulvoscopy with magnified vision and a focused light source. The patient should be placed in the lithotomy position and wear a sheet to cover her lower torso.

Internal Examination

For the speculum examination, a warm, lubricated speculum is used. The periurethral tissue or G-spot region is inspected (Figure 64.8) by lateralizing the arms of the speculum instead of the more common anterior–posterior approach. The vaginal wall is examined for the presence of vaginal rugae (Figure 64.9a and b), inflammation, discharge, color and thickness of the vaginal walls, and any vaginal lesions. Vaginal smear and wet mount is obtained. Vaginal pH is recorded. Single-digit palpation is achieved by gently placing a finger into the vaginal opening and depressing the bulbocavernosus muscle. Two fingers are placed against the lateral walls of the levator and underlying obturator muscles, which are assessed for tenderness. A rectovaginal and bimanual examination can be performed if indicated [34,47].

Neurourological Testing

Neurourological examination consists of sensory and reflex testing [47]. The sensory neurological exam evaluates the integrity of the three branches of the pudendal nerve including the dorsal nerve of the clitoris (sensation from the glans clitoris and clitoral shaft), the perineal nerve (sensation from the perineum and labia), and the inferior rectal nerve (sensation from the perianal skin). Testing is performed by assessing light touch (cotton ball or Q-tip) (Figure 64.10a) and pin prick (sterile needle) (Figure 64.10b). Testing sites include the right and left sides of the clitoral area, labia majora, labia minora, and perianal areas. The motor portion of the pudendal nerve is derived from the pelvic floor muscles. Sacral reflexes include the bulbocavernosus reflex and the anal wink reflex, and both sensory and motor arms of these reflexes are branches of the pudendal nerve. The afferent arm of the bulbocavernosus reflex is the dorsal nerve of the clitoris, and the efferent arm is the perineal nerve. The index and middle fingers are placed along the posterolateral aspect of either the right or left vaginal wall overlying the bulb of the clitoris, surrounded by the bulbocavernosus muscle. A gentle pinch of the glans clitoris with the opposite hand will elicit contraction of the bulbocavernosus muscle (Figure 64.11). The examination is repeated with the examining fingers facing the opposite vaginal wall. The afferent and efferent arms of the anal wink reflex both arise from the inferior rectal nerve. The anal wink reflex is performed using the wooden shaft end of the Q-tip and is assessed by touching the perianal skin, about 1 cm from the anus at the 3 o’clock and the 9 o’clock positions. Visible contraction of the anal sphincter will be noted after touching the skin [47].

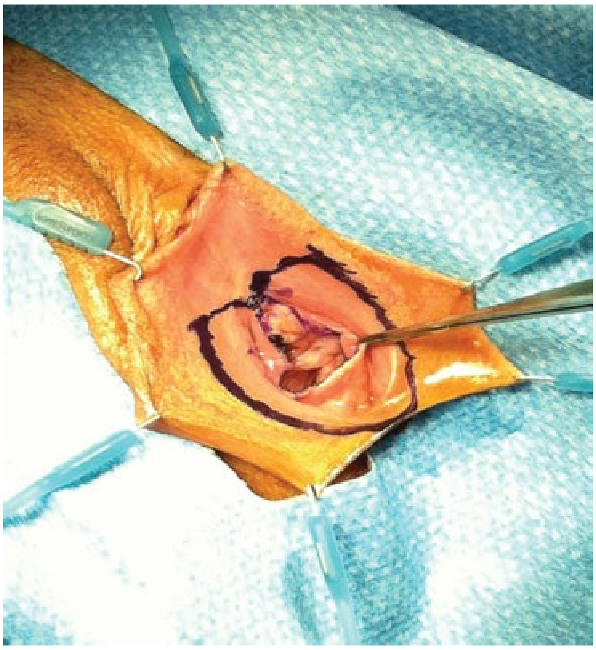

Figure 64.6 Hart’s line (here, outlined in blue ink at the beginning of a vestibulectomy).

Neurophysiological tests are not yet consensed so the history and physical examination remains the best methodology to screen for neurological causes for FSD. Objective sensory nerve testing may be performed with a biothesiometer (Figure 64.12a). This quantitative sensory test measures vibratory perception thresholds (expressed in volts) and values are obtained in a nongenital reference site (pulp index finger) as well as in multiple genital sites such as the glans clitoris (dorsal nerve of the clitoris) and the right and left labia minora (the perineal nerve). Other quantitative sensory testing involves determination of hot and cold perception threshold values in these test sites (Figure 64.12b) [34].

The health-care clinician may also perform a complete physical exam, such as examining for a thyroid goiter, to rule out other comorbid conditions that might be causing sexual dysfunction. A general physical exam is highly recommended in women with chronic illnesses and as part of good medical care, including a detailed breast exam and evaluation of blood pressure and heart rate.

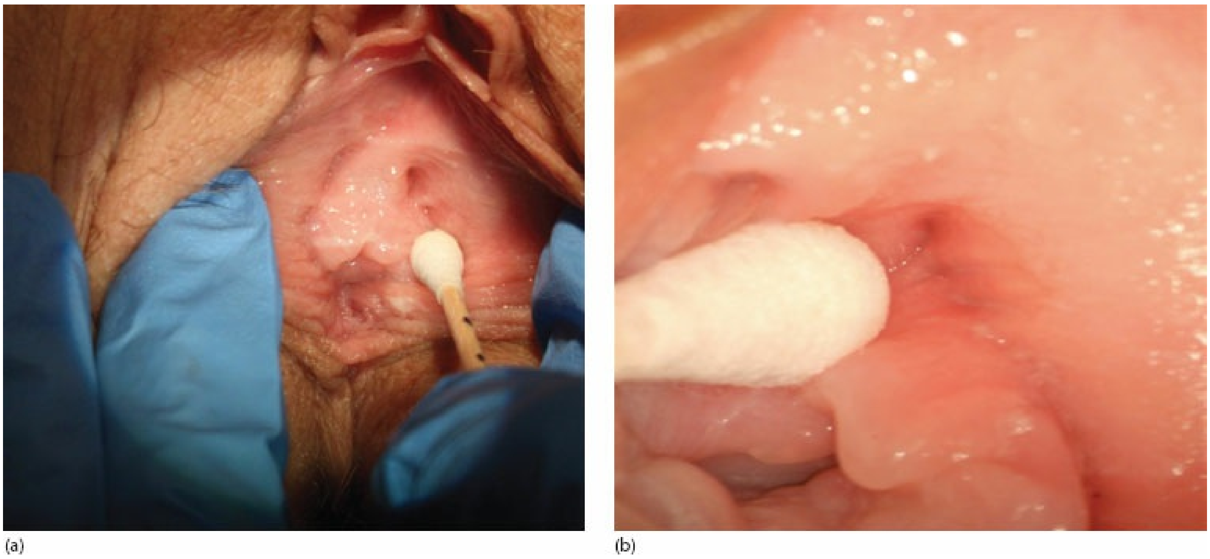

Figure 64.7 (a) A Q-tip cotton swab test is performed, gently applying pressure to the minor vestibular glands. This woman has no pain and no erythema overlying the minor vestibular glands. (b) This woman had pain, discomfort, and erythema overlying minor vestibular glands.

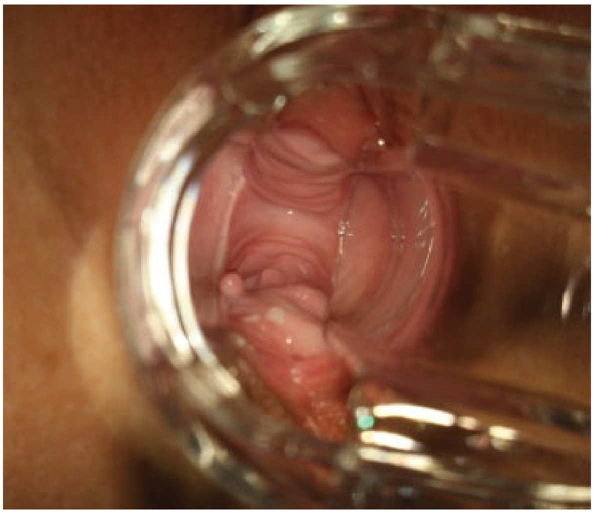

Figure 64.8 With the speculum turned horizontal, the periurethral tissue and G-spot region are inspected.

Laboratory Testing

There is no consensus on recommended routine laboratory tests for the evaluation of women with desire, arousal, and orgasm sexual health concerns. Blood testing should be dictated by clinical suspicion, especially from the results of the history and physical examination. If appropriate, the health-care clinician may assess multiple androgen and estrogen values [34] such as (nine hormone values) total testosterone, free testosterone, SHBG, DHT, estradiol, and progesterone. Pituitary function may be measured by obtaining luteinizing hormone (LH), FSH, and prolactin. TSH should be measured to exclude subclinical thyroid disease [34].

There are multiple concerns with the determination of serum hormone levels, especially testosterone [34–36]. The normal ranges of testosterone concentration values for women of different age groups without sexual dysfunction are not well defined. Testosterone levels reach a peak during the early follicular phase, with small but less significant variation across the rest of the cycle. Testosterone assays are not uniformly sensitive or reliable enough to accurately measure testosterone at the low serum concentrations typically found in women. Free testosterone is clinically more important than total testosterone in sexual function because the vast majority of testosterone is bound to SHBG and only a small amount of total testosterone is biologically available. The measurement of SHBG is relatively simple to perform with good reproducibility. Equilibrium dialysis is a highly sensitive assay for free testosterone; however, this method is not feasible for clinical practice. Measurement of free testosterone by analogue assays is unreliable. Free androgen may also be calculated using the free androgen index, defined as total testosterone (nmol/L) divided by SHBG (nmol/L). Calculated free testosterone may be determined and takes into account total testosterone, SHBG, and albumin. A calculator for the free testosterone is available online at http://www.issam.ch/freetesto.htm.

Androgens, including testosterone, not only are necessary for reproductive function and hormonal balance in women but also represent important precursors for the biosynthesis of estrogens. Historically, androgens were identified predominantly with male sexual function, contributing to a lack of recognition of the effects of androgens in women. We know that androgens have multiple biochemical effects in the body including but not limited to sexual desire, bone density, muscle mass and strength, mood, energy, and psychological well-being. However, sex steroid hormone actions are quite complex and involve critical enzymes and critical hormone receptors that also determine tissue exposure, tissue sensitivity, and tissue responsiveness.

(b)

Figure 64.10 (a) Neurological testing is performed by assessing light touch (cotton ball or Q-tip). (b) Neurological testing is performed by assessing the pain response to pinprick (sterile needle).

For example, in individuals, there are variations in the amount and activity of critical enzymes such as the 5-alpha-reductase enzyme, which is important in converting free testosterone into DHT. In our office, we have located a small subset of women who do not respond to typical doses of testosterone

(1/10 the dose for men), and we hypothesize that they have a deficiency in the 5-alpha-reductase enzyme [42]. We performed an IRB-approved retrospective chart review of 17 women examined between 2007 and 2013 who presented with persistent sexual side effects despite being treated with testosterone replacement therapy (TRT). Data collected included DHT, testosterone, SHBG, and calculated free testosterone values. The duration of use and duration of persistent side effects were recorded. Data from psychometrically validated questionnaires were assessed for parametric data analysis. Treatment regimens used in this study to achieve a free testosterone of 0.8 ng/dL were testosterone pellets labeled Testopel. The mean age of all 17 women was 57 years old. The mean pretreated testosterone values were 18.55 ng/dL; mean free testosterone values, 0.19 ng/dL; and mean DHT values, 10 ng/mL. After initial treatments with one testosterone pellet, the mean treated testosterone values increased to 141.89 ng/dL, mean free testosterone values to 1.40 ng/dL, and mean DHT values to 13.21 ng/mL. Since these patients continued to have persistent sexual side effects, we increased treatment in the 17 women to two pellets. The mean testosterone values increased to 174.50 ng/dL, mean free testosterone values to 1.61 ng/dL, and mean DHT values to 23.63 ng/mL with subsequent improvement in symptoms. No major adverse side effects were encountered in this study; however, two patients did experience mild acne and hair growth, which were both treated with local skin care. The mechanistic hypotheses to describe this phenomenon include persistent endocrine and epigenetic gene expression alterations of the 5-alpha-reductase enzyme. To improve symptoms in these patients, we have found that increasing the serum free testosterone levels above 0.8 ng/dL slowly drives DHT levels to the upper tertile of the normal range. Patients should be informed of possible persistent side effects of TRT and the need to drive testosterone values higher to see improvements in sexual side effects.

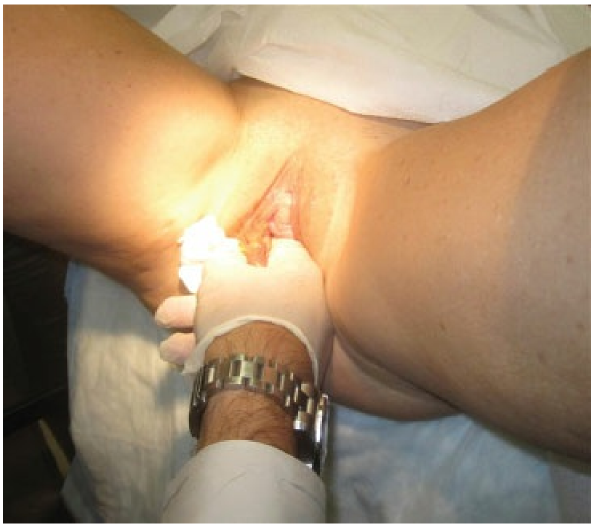

Figure 64.11 The afferent arm of the bulbocavernosus reflex is the dorsal nerve of the clitoris, and the efferent arm is the perineal nerve. The index and middle fingers are placed along the posterolateral aspect of either the right or left vaginal wall overlying the bulb of the clitoris, surrounded by the bulbocavernosus muscle. A gentle pinch of the glans clitoris with the opposite hand will elicit contraction of the bulbocavernosus muscle.

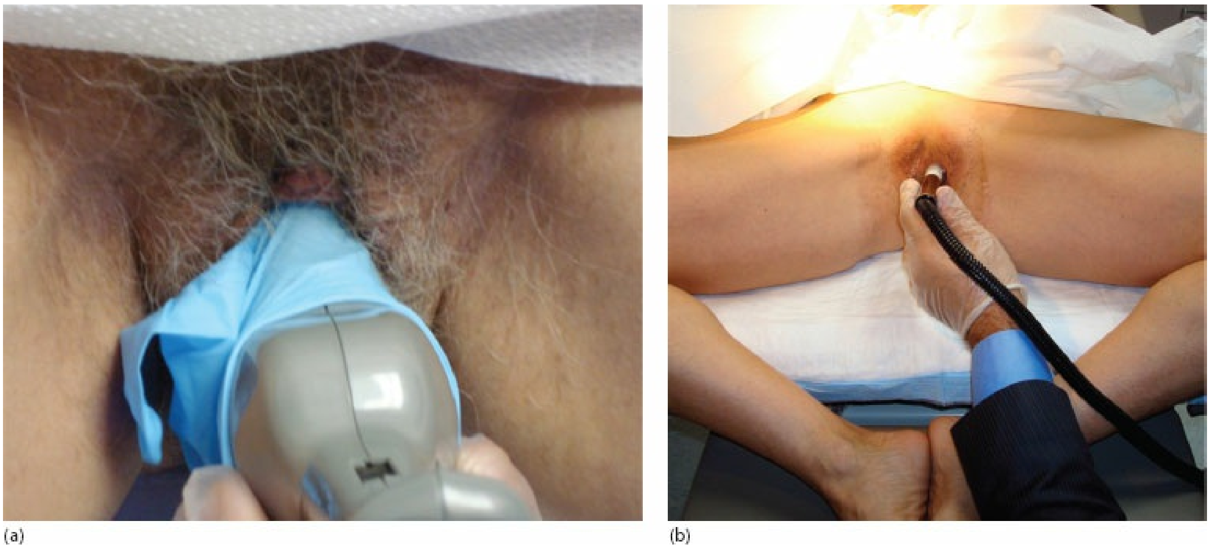

Figure 64.12 (a) A biothesiometer measures vibratory perception thresholds (expressed in volts) on a genital reference site (index finger) as well as in multiple genital sites such as the glans clitoris (dorsal nerve of the clitoris) and the right and left labia minora (the perineal nerve). (b) Quantitative sensory testing involves determination of hot and cold perception threshold values in the same test sites as the biothesiometer.

In addition, individuals have variations in individual sex steroid hormone receptor sequencing. Thus, independent of the values of sex steroid hormones, the unique individual variations in critical enzymes and sex steroid hormone receptors result in individual differences in tissue exposure, tissue sensitivity, and tissue responsiveness. More research is needed in the blood testing of sex steroid hormones in women with sexual health concerns.

Although there is a lack of clinical consensus as to the value, specificity, and sensitivity of individual hormone blood tests, there are evidence-based, placebo-controlled, double-blind data supporting the efficacy of exogenous sex steroid hormone treatment in women with sexual health concerns [34–36,43,44]. It is important to discuss with the patient the strategy of serial blood test surveillance testing to address safety concerns during such treatment.

Typical FSD Patient Assessment and Treatment Algorithms

Phase 1 (Local Tissue Hormone Supplementation)

It is important to emphasize that no single type of hormonal intervention or regimen will be effective in all women with desire, arousal, and orgasm sexual health concerns [34]. The hormonal abnormalities that are identified will determine which of the following biological treatment options women are offered in Phase 1.

Based on the history and physical examination, local estrogen treatment may be achieved with vestibular estradiol alone, intravaginal estradiol alone, or a combination of both. Local estrogen and testosterone, in the form of estradiol 0.03% + testosterone 0.1% in hypoallergenic base, improves vaginal perfusion, lubrication, tissue tone, and elasticity and restores the normal vaginal pH and vaginal health [32,33,45–49]. Vaginal estradiol also relieves dyspareunia, atrophic vaginitis, and vaginismus. Some systemic estradiol absorption occurs with all local vaginal estrogens, and regular estradiol blood testing may be necessary in some women. Daily application of a film of vestibular estrogen is recommended as well, because it promotes the health of the frenulum (the most sensitive part of the external genitalia), labia minora, urethral meatus, hymenal tissue, and vestibular glands [32,33,56–58].

The human vagina consists of three layers of tissue: the epithelium (composed of squamous cells), the lamina propria, and the muscularis (inner circular and outer longitudinal smooth muscle) [32,33]. The epithelium undergoes mild changes during the menstrual cycle. The lamina propria is replete with tiny blood vessels that become engorged with blood during sexual arousal, leading to lubrication. The smooth muscle of the muscularis enables the vagina to dilate and lengthen during penile penetration. Relaxation of that muscle leads to arousal. These three layers of tissue may function in an interrelated way. It is hypothesized that the blood vessels in the lamina propria that allow for lubrication are dependent on growth factors and that the growth factors are derived from the muscularis. Postmenopausal atrophy of vaginal tissues may be due to decreased synthesis of these growth factors resulting in a diminished number of critical blood vessels in the lamina propria [32,33].

Increased vaginal blood flow is an indicator of sexual arousal [50]. Genital swelling and lubrication are responses to increased clitoral and vaginal perfusion; increased length and diameter of the vaginal canal and clitoral corpora cavernosa; engorgement of the vagina wall, clitoris, and labia major and minora; and transudation of lubricating fluid from the vaginal epithelium. In animal studies [59], blood flow to the vagina was greatly reduced in the oophorectomized rats compared with the intact rats. Contrary to what one might expect, subphysiological doses of estradiol increased vaginal blood flow in oophorectomized rats more than either physiological or supraphysiologic doses. Ovariectomy-deprived estradiol values caused the vaginal epithelium to thin down to a single layer. Subphysiologic doses of estradiol increased the thickness of the vaginal epithelium the most because the oophorectomized rats had more estrogen-alpha receptors in the epithelium than the intact animals. A small amount of estradiol delivered to tissue with many estrogen-alpha receptors produced a huge response. Thus, estradiol regulates estrogen receptors through a negative feedback system. The muscularis, the muscle that enables the vagina to lengthen and widen during sexual arousal, also atrophies without estrogen. In postmenopausal women who do not take hormone therapy, the vaginal epithelium, lamina propria blood vessels, and muscularis all decrease. Like the epithelium, the muscularis responds to estradiol by increasing in thickness [59].

Women with sexual dysfunction who are placed on Phase 1 treatment (local estrogen/testosterone to the vestibule and into the vagina) need to undergo surveillance blood tests after 3 months of therapy to monitor the patient’s levels of estradiol, progesterone, DHEA, testosterone, androstenedione, DHT, FSH, LH, prolactin, and TSH as indicated. Women with desire, arousal, and orgasm sexual health concerns whose symptoms of distress are not resolved satisfactorily with Phase 1 treatments may consider progressing to Phase 2 treatments.

Phase 2 (Bioidentical Systemic Hormone Supplementation)

In Phase 2, women receive systemic estrogen and/or systemic testosterone (no FDA-approved testosterone replacement exists for women). Several clinical trials have shown that the distressing symptoms of vaginal atrophy associated with low-estrogen states are ameliorated after systemic estrogen therapy [34,54,56]. Low doses of systemic bioidentical nonsynthetic 17-beta-estradiol reduced vaginal atrophy compared with placebo in healthy menopausal women [34,54,56]. Systemic estrogen therapy can also successfully improve hot flushes, night sweats, and sleep disturbances that negatively affect body image, mood, and sexual desire. All efforts are made to keep serum estradiol levels between 30 and 50 ng/dL. The concept of maintaining estradiol values at low levels is to reduce the side effect risk while achieving a minimum efficacious dose [34]. Risks of systemic estrogen use should be discussed at length with the patient; they include breast cancer, heart attack, and stroke. In women with an intact uterus, systemic estrogen should always be opposed by a progestogen. All efforts are made to use bioidentical nonsynthetic progesterone and keep values in the range of 1 ng/dL [34].

Systemic testosterone (no FDA-approved testosterone replacement exists for women) has gained increased interest and use amongst clinicians treating FSD in their practice. The simple reason is that systemic testosterone supplementation can help alleviate a whole host of symptoms from dyspareunia in hormonally mediated vestibulodynia to low mood, desire, and libido. Systemic testosterone can be administered via transdermal application or intramuscular injection or with a pellet inserted into the adipose tissue of the buttocks. The dose for any systemic testosterone given to women is at one-tenth the dose administered to men. When checking laboratory values, it is important to keep women in a range of free testosterone between 6–8 ng/dL. In addition, we check a DHT value, which we aim to keep in the upper tertile range, since on occasion women with a free testosterone between 6–8 ng/dL may still be symptomatic. In that scenario, we hypothesize that there is a downstream abnormality or deficiency in the 5-alpha-reductase enzyme, and thus, the testosterone value will have to be increased to offset the lower DHT. Finally, if side effects like male pattern balding or facial hair or acne become a problem, low dose 5-alpha-reductase inhibitor (finasteride 1 mg) once to twice a month can be administered.

Systemic androgens (systemic DHEA and/or systemic testosterone) have been shown to improve mood, energy, stimulation, sensation, arousal, and orgasm in women with sexual health concerns.

Limited clinical trials have examined the effects of systemic DHEA therapy on sexual function in women [51–53]. Baulieu and colleagues [56] administered systemic DHEA (50 mg) or placebo to 140 women between the ages of 60 and 79 years for 12 months. Systemic DHEA treatment produced approximately a doubling of serum total testosterone concentration and also significantly increased skin hydration and bone density. Libido was increased after 6 months of treatment; sexual activity and sexual satisfaction were both increased after 12 months [56]. One benefit of administering systemic DHEA and systemic testosterone is that these hormones will endogenously aromatize to estradiol, thus relieving hot flashes and night sweats without the administration of systemic estrogen [34].

Systemic testosterone has been used to treat women with sexual dysfunction since the 1940s [54]. Transdermal patches or gels or subcutaneous pellets are being studied for their safety and efficacy in reducing sexual symptoms associated with testosterone insufficiency [34–36]. Transdermal testosterone patches have been compared with placebo in estrogenized women who had undergone oophorectomy and hysterectomy. One study [55] showed that the 300 μg testosterone patch was significantly more effective than the 150 μg patch or placebo in improving frequency of sexual activity, pleasure, and fantasy during a 12-week period.

Phase 3 (Nonhormonal Medication)

In phase 3, attention is given to the possible role of dopamine agonists (only one FDA-approved nonhormonal medication exist) in facilitating desire and orgasm sexual responses [56–58]. Sexual motivation is encouraged, sustained, and ended by a number of central nervous system neurotransmitter and receptor changes induced, in part, by the action of sex steroids, androgens, estrogens, progestins, and the central neurotransmitter dopamine [60]. The activation of dopamine receptors may be a key intermediary in the stimulation of incentive sexual motivation and sexual reward. These neurotransmitters and receptor changes in turn activate central sexual arousal and desire. Contemporary animal research reveals that dopamine neurotransmitter systems may play a critical intermediary role in the central regulation of sexual arousal and excitation, mood, and incentive-related sexual behavior, in particular, in the motivational responses to conditioned external stimuli. In summary, the complex central neurochemical actions of neurotransmitters stimulate sensory awareness, central sexual arousal, mood, and reward, which relates to relevant individuals' sexual experiences involving a partner, a place, and an action [60].

Bupropion, which is a noradrenaline and dopamine reuptake inhibitor with nicotinic antagonist properties originally marketed as an antidepressant, may have a beneficial effect on women with hypoactive sexual desire disorder [34,57,58]. In a placebo-controlled trial [62], bupropion produced an increase in desire and frequency of sexual activity compared with placebo. Traditional dosing starts at 150 mg twice a day; we have found that low dose of 75 mg twice a day achieves an optimal improvement in sexual dysfunction symptoms. Other dopamine agonists used are cabergoline administered at 0.5 mg up to three times per week, and ropinirole 0.25 mg administered daily [56]. Oxytocin lozenges, linked to improved arousal and desire, are administered at 250IU sublingual 30 minutes to 1 hour before sexual activity. Research with oxytocin has shown marked improvement in a number of components of sexual function, including libido, erection, and orgasm [59]. Amphetamines like Adderall and other drugs used to treat attention deficit disorder have been increasingly useful in helping women to concentrate and thus improving orgasmic response and intensity [60].

Currently, there is one drug that is FDA approved, flibanserin, which is a drug that clinically has been shown to improve hypoactive sexual desire disorder. Specifically, flibanserin works by diminishing serotonin release by serotonin 1A agonism and also inhibits binding to the serotonin 2A receptor involved in inhibitory cortical outflow. It further acts to increase dopamine and noradrenalin [61].

Vasodilators

Basic science studies [62,63] investigating the physiology of sexual function utilizing female animal models support the role of nitric oxide cyclic guanosine monophosphate phosphodiesterase type 5 pathways in the peripheral arousal physiology of the clitoral corpus cavernosum, corpus spongiosum, vaginal epithelium, and vaginal lamina propria.

There have been several clinical studies [64–66] on selective phosphodiesterase inhibitors (PDE5i) over the last few years, conducted with either premenopausal or postmenopausal women with arousal sexual health concerns as well as healthy women without sexual dysfunction. Many studies did not take into account the hormonal milieu of the subjects in the inclusion and exclusion criteria. An important point in treating women with arousal sexual health concerns is that an adequate sex steroid (androgen and estrogen) hormonal milieu is critical for benefits from selective phosphodiesterase inhibitor treatment.

One study, a double-blind, crossover, placebo-controlled safety and efficacy study [70] with selective PDE5i, was performed in premenopausal women with normal ovulatory cycles and normal levels of steroid hormones who were affected by female sexual arousal disorder without hypoactive sexual desire disorder. Subjects were observed to benefit from treatment with the active selective PDE5i, showing improvement in sexual arousal, orgasm, frequency, and enjoyment of sexual intercourse versus placebo. Nurnberg found that sildenafil significantly improved sexual function, especially orgasm in women whose free testosterone values were in the normal range and also in women who developed sexual health problems following use of selective serotonin reuptake inhibitors [71].

Sexual Pain Management

Biological pathophysiologies resulting in women's sexual health problems associated with sexual pain may occur in the clitoris, urethra, bladder, vulva, vestibule, vagina, and pelvic floor muscles.

Clitoris, Prepuce, and Frenula

In women with focused clitoral pain, clitoral itching, or clitoral burning, careful inspection of the glans clitoris should be performed [67]. Failure to visualize the whole glans clitoris with the corona is consistent with some degree (mild, moderate, or severe) of preputial phimosis, based on the elasticity of the prepuce and its ability to retract on examination. Since phimosis may create a closed compartment, phimosis is often the underlying pathology in clitoral glans balanitis associated with recurrent fungal infections. Initial treatment may be conservative with topical estrogen and/or testosterone creams to see if the prepuce can be made more elastic and retractile. Topical antifungal agents such as nystatin or oral antifungal agents such as fluconazole may be considered. Infections can also be related to herpes virus, with appropriate treatment administered such as acyclovir. If conservative treatment fails due to the phimotic prepuce, surgical management by dorsal slit procedure should be considered [72].

Urethral Meatus

Gentle retraction of the labia minora should provide full view of the urethral meatus. Prolapse of the urethral mucosa out of the urethral lumen is highly associated with estrogen deficiency states such as following bilateral oophorectomy, natural menopause, or following chemotherapy for malignancy. Clinical symptoms include urgency, frequency, and discomfort on urination as well as spotting of blood, which may be observed on the toilet paper after wiping following voiding. The abnormal voiding history is often accompanied by a unique sexual history. Women with urethral prolapse often have the ability to have full sexual pleasure and satisfaction during self-stimulation of the clitoris; however, during sexual activity with the partner or with a mechanical device, she experiences pain and/or urgency to urinate and/or inability to have orgasm secondary to distracting pain. Conservative treatment options include topical or systemic estrogens, although the risks and benefits of estrogen treatment need to be fully discussed.

Vulva/Vestibule

Genital sexual pain in the vulva/vestibule may be related to varied specific disorders [40,68,69]. The treatment of any genital sexual pain disorder involves the multidisciplinary team approach, and this is especially true for the disabling condition of vestibulodynia. Patient management includes education and support, especially regarding avoidance of contacts and practice of healthy vulval hygiene, pelvic floor physical therapy treatment, management of concomitant depression, and management of any associated neurological, dermatological, gynecological, orthopedic, or urological conditions.

HORMONALLY MEDIATED VESTIBULODYNIA

Hormonally mediated vestibulodynia symptoms are similar to those of neuroproliferative but seen more commonly in young girls who have been exposed to birth control pills or menopausal women. Symptoms include vaginal dryness, dyspareunia, itching, burning upon palpation of the vestibule. On physical exam, the vulva may appear atrophic and resorbed, the clitoris can be shrunken, and the telltale sign of hormonally mediated vestibulodynia is an inflamed and painful vestibule and periurethral glands. These are provoked with a Q-tip and are graded on a 0–10 pain scale. The hormonally depleted vagina typically has lost the rugae, has a pale complexion, has a lack of lubricating substance, and will bleed with minimal contact. On wet mount, the microscopic examination reveals parabasal cells and increased white blood cells. The vaginal pH is typically elevated to 6.0–7.0 (normal 4–4.5). Conservative treatment begins with local topical and intravaginal estrogens. Important, however, is to address the testosterone receptors within the vestibule as this tissue is derived from the endoderm compared with the estrogen-rich ectoderm of the vulva and the vagina-derived mesoderm. We routinely will have these patients apply a compounded 0.01% testosterone + 0.3% estrogen cream to the vestibule and into the vagina.

NEUROPROLIFERATIVE VESTIBULODYNIA

Neuroproliferative vestibulodynia is a disorder seen more commonly in younger women who has either been living with vestibular pain since they can remember (congenital) or developed symptoms over time, consistent with neuroproliferative vestibulodynia. Typically, these women have failed conservative management first: physical therapy, hormone replacement (if necessary), medical management like tricyclic antidepressants or gabapentin, topical xylocaine/lidocaine, and positive VAT. When the VAT is positive, the patient is offered a complete vestibulectomy (Figure 64.13a and b), which is a surgical procedure in which the entire vestibule and associated glands are surgically excised.

Dermatological Conditions

Lichen Sclerosis

Lichen sclerosis [44] (Figure 64.14) is a chronic genital dermatitis condition that is associated with varying intensity of symptoms including vulval itching and/or burning and various degrees of vulval scarring leading to narrowing of the introitus and with subsequent dyspareunia. The typical presentation of burning and itching symptoms can be so intense as to severely interfere with sexual activity, day-to-day activities, and even sleep. If the scarring of lichen sclerosis involves the perianal area, the patient may also complain of perianal fissuring and painful defecation. The diagnosis of lichen sclerosis is suspected by physical examination showing a white color genital, vulval, and vestibular tissue with paleness, loss of pigmentation, and characteristic “cigarette paper” wrinkling. Classically, the genital tissue changes do not involve the inside of the vagina, and if they involve the perianal area, there is a traditional “figure of eight” extension. The lichen sclerosis condition commonly involves the vestibule with associated labia minora atrophy and the vaginal introitus with loss of elasticity and narrowing [44]. Diagnosis is confirmed with a biopsy of the affected areas. Once a diagnosis is made, treatment with clobetasol 0.05% topical cream is applied to all affected areas daily for 12 weeks and then decreased to 3 times a week. For more severe disease, 10% hydrocortisone acetate is compounded in a vaginal cream, and 3–5 g (300–500 mg) is inserted nightly for 2 weeks and then decreased to Monday, Wednesday, and Friday. There are no safety data on these products and local atrophy may occur. Yeast infections must be suppressed using fluconazole 150 mg weekly. Adrenal axis suppression can occur with prolonged use [70]. Failure to respond may require more specialist gynecological, dermatological, or plastics support.

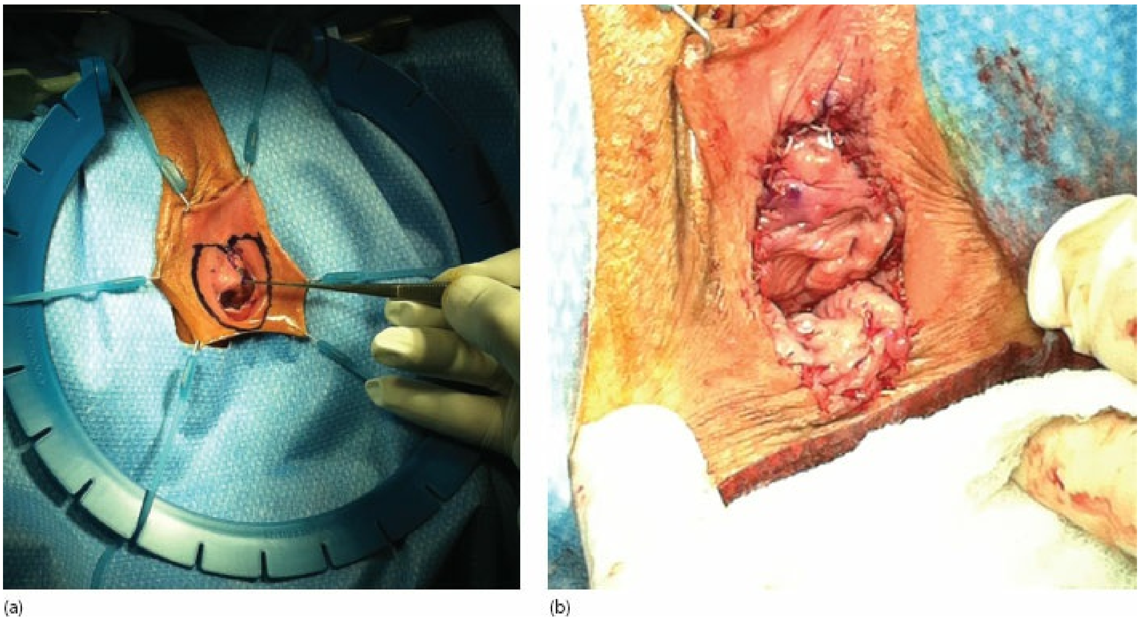

Figure 64.13 (a) Complete vestibulectomy with vaginal advancement flap includes excision of the vestibular mucosa adjacent to the urethral meatus/Skene's glands region anteriorly. (b) Picture from the end of a vestibulectomy. All vestibular mucosal tissue has been removed, laterally and posteriorly, with reconstruction including the posterior vaginal flap advancement.

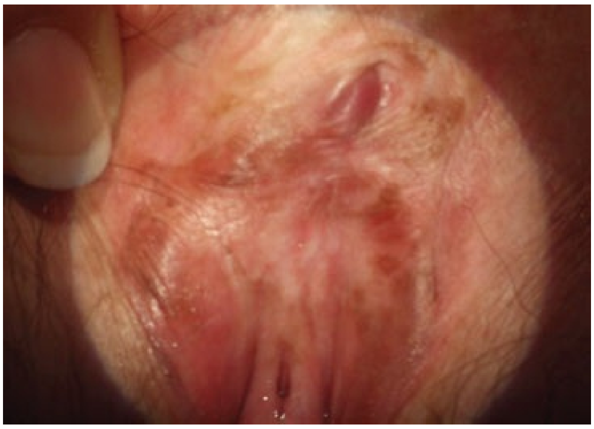

Figure 64.14 Lichen sclerosis is diagnosed by physical examination. The typical presentation is genital, vulval, and vestibular tissue with paleness, loss of pigmentation, and characteristic "cigarette paper" wrinkling. Classically, the genital tissue changes do not involve the inside of the vagina. Lichen sclerosis commonly involves the vestibule with associated labia minora atrophy and the vaginal introitus with loss of elasticity and narrowing.

Lichen Planus

Lichen planus is another chronic genital dermatitis condition, which is likely to have a pathophysiology related to varied altered immunological disorders, and as a result, the presenting symptoms may vary widely. Lichen planus may occur secondary to drugs, such as antihypertensives, diuretics, oral hypoglycemics, and nonsteroidal anti-inflammatory agents. One presentation is primarily associated with itching and does not result in scarring. Another is erosive and destructive. Overall, patient complaints may include severe vulval itching, pain, burning, and irritation similar to lichen sclerosis. Dyspareunia occurs secondary to vaginal introital scarring. Some types of lichen planus, unlike lichen sclerosis, may involve the vaginal mucosa. If there is vaginal involvement, a purulent malodorous discharge may be noted. Findings on physical examination of women with lichen planus vary widely. The pruritic type of lichen planus is associated with a purple color and multiple papules and plaques on the vulva and vestibule. The erosive type is associated with vestibular ulcers, scarring, clitoris and labia minora atrophy, and occasionally destruction of the vagina has been reported [44]. Similar to lichen sclerosus, biopsy proven disease with lichen planus is treated similarly with a topical steroid, clobetasol 0.05%. Daily treatment may be needed for 8–12 weeks to gain adequate control. Education is very important here. The patient needs to know exactly where to apply the ointment and how much. A diagram is very useful and a clinical photograph of the female patient's affected area is even better. For long-term use consider intermittent application, such as treatment on Monday, Wednesday and Friday, or switch to a low potency steroid. If there is concern about recurrent yeast infections prescribe oral fluconazole 150 mg weekly for suppression.

DIV

Women who present because of a qualitative or quantitative alteration in vaginal discharge should be evaluated by clinical examination and appropriate laboratory tests, such as pH and microscopy. Bacterial vaginosis, vulvovaginal candidiasis, and trichomoniasis vaginitis are the most common causes of vaginal discharge in premenopausal women. When these conditions have been excluded, other causes of vaginal discharge must be considered in the differential diagnosis of women with vaginal complaints. Desquamative inflammatory vaginitis (DIV) (Figure 64.15a and b) is a chronic clinical syndrome of unknown etiology. Most investigators believe that it is primarily an inflammatory vaginitis of noninfectious etiology, with secondary bacterial microbiota disruption [71].

DIV is characterized by pain (dyspareunia, vaginal/introital pain, burning) with diffuse exudative vaginitis and epithelial cell exfoliation, resulting in profuse vaginal discharge (usually yellow but may be gray or green). In a large series of 98 patients diagnosed with DIV (mean age 49.6 years), 70%–90% had purulent vaginal discharge, dyspareunia, and vaginal inflammation [72]. Treatment is aimed at alleviating the chronic discharge with various compounded mixtures of antibiotics, steroids, and hormones applied topically to the inside of the vagina as a suppository. Currently, we use a compounded vaginal suppository of 10% hydrocortisone + 2% clindamycin + 0.02% estradiol. Anytime a treatment regimen involves a strong steroid like hydrocortisone or clobetasol, antifungal should be used since resultant yeast infections can be common.

Surgery

Surgical Treatment for Neuroproliferative Vestibulodynia

Surgical intervention for management of women with neuroproliferative vestibulodynia is offered to those who have failed initial conservative medical, psychological, and/or physical therapy focused treatment. Surgery is based on the hypothesis that the pathophysiology of neuroproliferative vestibulodynia is associated with inflamed, irritated, and hypersensitive vestibular glandular tissue and related increased nerve density in the vestibular mucosa. Surgical success is therefore based on excision of this abnormal glandular and nerve tissue in the vestibule. In women with neuroproliferative vestibulodynia, the procedure entitled complete vestibulectomy with vaginal advancement flap includes excision of the vestibular mucosa adjacent to the urethral meatus/Skene's glands region anteriorly, excision of vestibular mucosa laterally, and posteriorly to the hymen with reconstruction including the posterior vaginal flap advancement (Figure 64.13a and b). This procedure is usually performed under general or regional anesthesia.

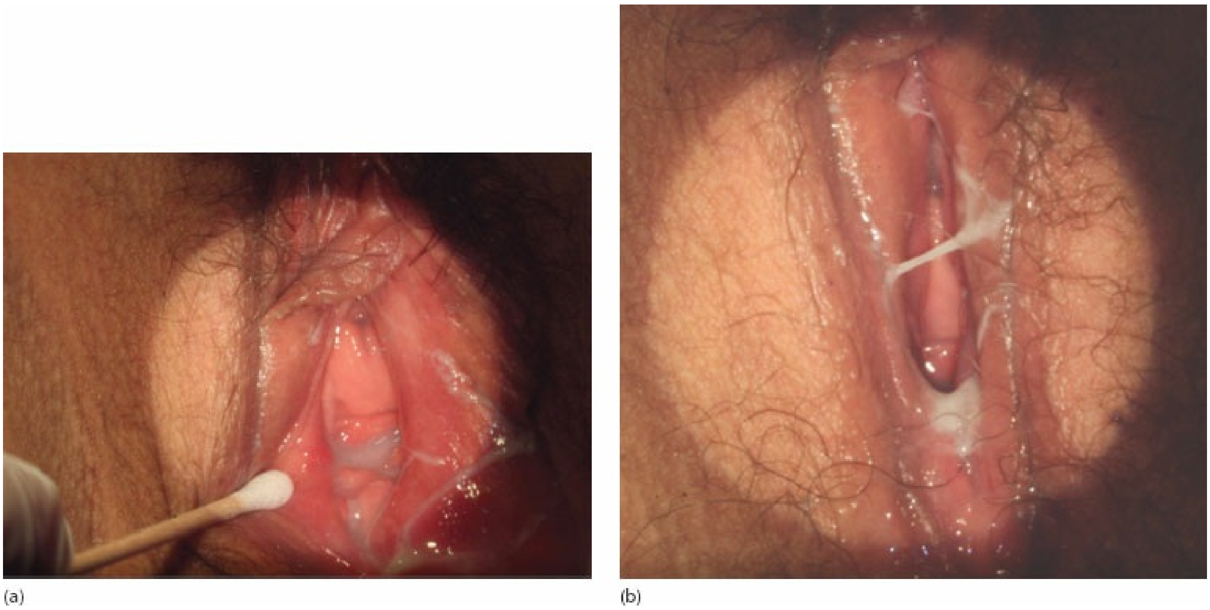

Figure 64.15 (a and b) Desquamative inflammatory vaginitis. Copious yellow discharge, usually described by patients as “dries like glue” and “sticks to underwear.” Under microscopy, we see leukorrhea and parabasal cells.

Complications include bleeding, infection, increased pain, hematoma, wound dehiscence, vaginal stenosis, scar tissue formation, and Bartholin duct cyst formation. During vestibulectomy, the vaginal advancement may cover the ostia of the Bartholin glands; however, the risk of postoperative Bartholin gland cyst formation is only 1%. As always with surgery, the risk of these complications can be reduced with appropriate surgical techniques. Various closure techniques have been described to minimize the risks of postoperative complications. Specifically, the vaginal advancement flap should be anchored by multiple interrupted horizontal mattress sutures of 3-0 Vicryl placed in an anterior–posterior direction. The remaining mucosal flap is then approximated to the perineum with interrupted stitches of 4-0 Vicryl. Intraoperative bupivacaine extended-release liposome is applied conservatively to the dissected tissue to aid in 72 hours of postoperative recovery. Postoperative care includes oral opioid pain medications for the first few weeks, including warm baths nightly. At 6 weeks postoperative follow-up, we will (1) perform vulvoscopy and a vaginal ultrasound to determine for the presence or absence of Batholin’s cysts and (2) perform a Q-tip test to see if any recurrent glands are causing pain. Ultrasound allows visualization of Bartholin cyst formation. We have found that cysts >10 mm, when painful, are easily drained via intraoperative marsupialization.

CONCLUSIONS

In a comprehensive textbook on *female urology and urogynecology*, it is important and appropriate to have a detailed chapter on the biologically focused management of women’s sexual health concerns. In the twenty-first century, in medicine, increasing numbers of health-care clinicians will need to be able to manage women with sexual health concerns since more and more women will expect and demand such management. In addition, those health-care clinicians who want to maximize overall women’s health-care delivery will increasingly engage in the management of women’s sexual health concerns, in addition to the traditional focus on continence and urological conditions. The need to address these issues is such that in future it will be increasingly more difficult for female urologists and urogynecologists to not provide at least first-line sexual health care to women.

The basic premise of biologically focused management of women’s sexual health concerns is that the normal physiological processes regulating sexual activity can be altered by biological pathology. How each specific medical condition modulates women’s sexual health requires increased intensive basic science investigation. From the perspective of biologically focused clinicians, identification of the underlying pathophysiology of the sexual dysfunction is essential. If the biological basis of the sexual health concern can be diagnosed by history and physical examination and laboratory testing, management outcome may be successfully directed to the source pathophysiology. Of the many challenges facing health-care professionals today, the first is to improve the ability to accurately diagnose women with sexual health concerns, and the second is to ensure that women receive the best evidence-based available management options. The biologically focused clinician needs to have access to new developments in evidence-based, state-of-the-art data concerning biologically focused management strategies for women's sexual health concerns. As stated earlier, membership in specialized societies such as the International Society for the Study of Women's Sexual Health (ISSWSH) will help the interested clinician achieve this goal.

ISSWSH

Clinicians who are particularly interested in women's sexual health or want to improve their clinical management skills may wish to become members of the ISSWSH, an international, multidisciplinary, academic, clinical, and scientific organization. The purposes of the ISSWSH are to provide opportunities for communication among scholars, researchers, and practitioners about women's sexual health; to support the highest standards of ethics and professionalism in research, education, and clinical practice relative to women's sexual health; and to provide the public with accurate information about women's sexual health. Interested health-care professionals should visit the organization's website: http://www.isswsh.org.

65 Multidisciplinary Team

Kaori Futaba, Simon Radley, and Matthew Parsons

MULTIDISCIPLINARY TEAM

Pelvic floor pathology in women encompasses a wide spectrum of functional, anatomical, neurological, hormonal, and neoplastic conditions that may be associated with symptoms of bowel, urinary, and/or sexual dysfunction [1]. The realization that the pelvic floor does not exist in isolation is an important concept that must be explored [2]. Functionally, the pelvis is multicompartmental, and so it is important to ask the right questions to assess patients. A review performed by Davis and Kumar in 2003 found that patients only reported their most severe symptoms and often did not report symptoms of incontinence or sexual dysfunction as they felt it was not worthy of attention. Patients often volunteered limited information due to shame, cultural beliefs, stereotyping, and self-blame [3]. Many symptoms of pelvic floor dysfunction are of a personal and sensitive nature and use of a self-completed questionnaire may be a valuable method of assessment to obtain accurate information on symptoms that are important to the patient [4]. Patients can complete the questionnaires in private and take as long as required.

Questionnaires can be used as a screening tool to carry out a comprehensive assessment of the whole pelvic floor to identify patients who may have more than one compartment symptomatology and who may benefit from a multidisciplinary assessment and treatment. The Birmingham Bowel and Urinary Symptoms Questionnaire (BBUSQ-22) is a 22-item questionnaire encompassing all aspects of pelvic floor function including constipation, evacuation, incontinence, and urinary symptoms in women [1]. The electronic personal assessment questionnaire-pelvic floor (ePAQ-PF) is a one-item-per-page touchscreen questionnaire with interaction allowing detailed questioning and skipping. It comprises four dimensions: 35 urinary, 33 bowel, 22 vaginal, and 28 sexual items. Each domain is scored 0–100. ePAQ-PF also scores how much each symptom bothers them on a four-point scale producing a one A4 page summary providing an overview as well as details of the pelvic floor problems [5]. There are many individual symptomatic severity scores and quality of life assessments available as summarized in Table 65.1. They may be useful for assessment pre- and posttreatment.

There are many benefits in developing a pelvic floor multidisciplinary team (MDT). The Calman–Hine report, published in 1995, proposed an MDT approach for the management of colorectal cancer, which is now well established [21]. MDT working already plays a key role in the management of benign diseases such as inflammatory bowel disease. The pelvis has been anatomically and functionally divided into an anterior compartment (the bladder), a middle compartment (the vagina), and a posterior compartment (the rectum), each compartment cared for in isolation. It has been suggested for over two decades that pelvic floor disorders would be better managed through the collaborative efforts of gynecologists, urologists, colorectal surgeons, psychologists, physiotherapists, neurologists, and radiologists [22].

Patients with complex pelvic floor conditions can be discussed with the members of the MDT, particularly when more than one compartment is affected. The team can share ideas and experiences to reach a consensus on the best treatment options, some of which may involve combined operating. It is estimated that one in nine women will undergo surgery for pelvic floor disorders during their lifetime and that 30% of these patients will require further surgery for the same condition [23]. With pelvic floor disorders, the correlation between structural abnormality and function is not always straightforward [24]. Organ-specific approach in the management of pelvic floor disorders may result in partial treatment of their global pelvic floor dysfunction, leading to high recurrence rate [25]. Harold Drutz, the ex-president of the International Urogynecological Association, at the 21st annual clinical meeting in Vienna in 1996, commented that “we have done women a tremendous disservice by fractionating health care for pelvic floor disorders and that there needs to be increasing dialogue, not monologue, between urologists, urogynecologist, gynecologists and colorectal surgeons” [26].

The interdisciplinary, multiprofessional pelvic floor MDT meeting provides an excellent environment for the team to develop expertise collectively and encourage best evidence-led practice, improving patient care and satisfaction [27]. It provides a valuable way of managing difficult cases as well as streamlining management [24]. Cross-specialty MDT allows decisions to be made about patients without the need for face-to-face consultations in each case. Patients for surgery can be discussed to ensure that the right operation is being offered to the patient, but the MDT meeting can also help in discussing complex patients in whom we may not be able to offer a surgical solution for their symptoms. These patients, knowing that their cases have been discussed with all members of MDT, may accept such a decision more readily. It will also allow standardization of care across different units, building a link between different specialties and simplifying referral pathways. It is important to appreciate that the pelvic floor MDT is not just about meeting once a month but is integral to patient care.

The pelvic floor MDT meeting also allows an opportunity to discuss important topics, which may be suitable for a cross-specialty audit or to carry out clinical trials to improve patient care. Comparison of studies in the literature carried out by different specialties for the same condition in the past has been difficult as there has been lack of uniformity in assessment and scoring, for example, different descriptions and grading of prolapse [28].

Table 65.1 Severity Score and Quality of Life Questionnaires

Severity score	**Quality of life score**
Urinary incontinence (UI) [6]	
Incontinence Severity Index [7]	Incontinence Quality of Life Questionnaire [8]

Wexner incontinence Grading Scale [18]	Fecal Incontinence Quality of Life Scale [19]
St. Mark’s Incontinence Scores [20]	EQ-5D

In Birmingham, the pelvic floor MDT meeting takes place on a monthly basis with sufficient time set aside to discuss the cases. Online patient records and radiological imaging allow us to discuss patients and their imaging and investigations. An attendance register is kept. Minutes are kept from each meeting, and letters detailing discussion and decisions are written to the patients’ primary care physician and other involved parties. Copies of the correspondence are usually also sent to the patients.

The pelvic floor MDT needs to be inclusive of all the members and should include the following [25,27]:

Urogynecologists: To offer specialist input into the investigation and management of conditions affecting the anterior and middle compartment.

Colorectal surgeons with specialist interest in pelvic floor disorders. To offer specialist input into the investigation and management of conditions affecting the posterior compartment.

Urologists with specialist interest in pelvic floor disorders. To offer specialist input into the investigation and management of conditions affecting the anterior compartment.

Specialist radiologists and radiographers: Expert interpretation of specialized investigations such as transit study, defecating proctogram, and MR proctogram.

Medical gastroenterologists with interest in dysmotility. Gastroenterologists play a key role in the medical management of patients with functional bowel disorders. Most male and nulliparous women present through the medical clinic.

Physiologist: Carries out GI physiology investigations including endorectal ultrasound scans and anorectal physiology. They may also be involved in programming and follow-up of patients with sacral nerve stimulators.

Midwives: Midwives with specialist expertise in managing patients who have sustained previous obstetric sphincter injuries. They play an important role in supporting patients at a challenging time post obstetric injuries but also in counseling patients who has had previous obstetric injury decide how to deliver with subsequent pregnancies.

Specialist nurses: Nurse specialist with interest in managing pelvic floor dysfunction such as urinary or fecal incontinence. Plays a key role in providing patients support, education, and teaching patients how to perform some of the conservative treatments such as self-catheterizations and rectal irrigations. Helps to reinforce the advice given by the rest of the MDT in clinics.

Physiotherapists: Offers postpartum pelvic floor rehabilitation, as well as targeted biofeedback sessions for patients with incontinence.

Dieticians: Offers patients advice on dietary intake, which may have a profound effect on their abdominal and bowel symptoms.

Clinical psychologists: Some patients may have complex psychological issues, who would benefit from combined treatment with psychologists. Behavioral modification techniques are just as important as surgical treatments [26].

Chronic pain specialists: Patients with chronic pain, not managed by simple measures, may benefit from assessment and other alternative treatments by the chronic pain team.

The clinician in charge of the patient’s dominant symptom usually coordinates assessment and treatment. In some units, patients with pelvic floor disorders are managed in a combined pelvic floor clinic allowing patients to be assessed by different specialties in one clinic. A dedicated specialist led pelvic floor clinic offers several advantages including key members of the MDT to be present in one clinic and adequate time available for comprehensive clinical assessment, review, and discussion of results to decide on the best treatment. It also offers a comprehensive training opportunity for trainees. It is essential as a unit to decide on how patients are identified, who would benefit from a review in the combined pelvic floor clinic, and which members of the MDT should attend. The MDT meeting provides the ideal filter for the combined clinic. Decisions can be made as to which women will specifically benefit from a combined clinic appointment. While the benefits of a combined clinic may seem evident, such clinics are necessarily labor intensive and not necessarily cost effective in overall health-care delivery. More than one senior clinician can spend a considerable length of time with an individual patient and this is clearly not achievable for all. However, joint clinic may allow patients to be managed efficiently avoiding multiple trips to different hospitals for investigations and clinic appointments, waiting several weeks in between each episode. A telephone survey performed on 165 patients’ experience with the multidisciplinary pelvic floor clinic in Canada showed that the majority of patients were satisfied and accepting of a multidisciplinary approach to pelvic floor dysfunction [29].

In Birmingham, patients who have sustained obstetric third- or fourth-degree tears are routinely reviewed 12 weeks postpartum in the Obstetric Anal Sphincter Injury Services clinic once a month. Patients are assessed by midwives, urogynecologists, and colorectal surgeons [30] according to their symptoms. Most will not require any interventions other than advice and reassurance regarding subsequent deliveries. Many are happy that we offer an opportunity for cesarean delivery in future pregnancies if they prefer; most choose vaginal birth that is appropriate in the majority of cases. Identifying symptomatic women in the combined clinic allows them early access to investigation and treatments (most of which are nonsurgical) as well as appropriate support and counseling as required. New women are seen by a clinician who completes a standard proforma. This ensures all the appropriate questions are asked to identify symptoms. It also provides a useful audit tool.

Adjacency of clinic rooms means that advice is readily available from the subspecialists present as required. Lower urinary tract symptoms and minor anal (other than incontinence) or vaginal symptoms are particularly common in this group of women [31].

The delivery of a modern pelvic floor service is more demanding and complex than ever. An effective service requires a group of enthusiastic clinicians and allied health-care professionals with an interest in managing patients with pelvic floor disorder to work in tandem. We believe that there is a role for a combined clinic, but the use of the MDT meeting and global symptoms scoring system allows us to identify which patients will derive most benefit from such a clinic. The unit also requires the basic diagnostic infrastructure and provision of a comprehensive range of treatments. Patients can be diagnosed accurately, and treatment options can then be discussed with adequate information on realistic outcomes and possible complications. The spectrum of therapeutic options in pelvic floor conditions has increased enormously in the last decade, offering an exciting challenge for the future [27].

66 Multidisciplinary Clinic: Urology and Urogynecology

Pallavi Latthe

INTRODUCTION

Functional disorders account for a large amount of the medical activity, including in urology. The decreased quality of life due to lower urinary tract symptoms (LUTSs) requires prompt management with primary assessment preferably in the community. Referral to a specialist is required when simple management has failed and whenever any of the following coexists: hematuria, recurrent urinary infection, prolapse, masses, or neurological conditions [1].

The concept of multidisciplinary specialty clinics has evolved in order to provide comprehensive, coordinated, and the best possible care for patients with complex diseases or where these cover more than one traditional service boundary. These models have repeatedly been shown to improve clinical outcomes in a variety of conditions [2].

A multidisciplinary team (MDT) is the key to accurately assess patients with regard to their bother and handicap, therefore offering the most appropriate conservative, medical or surgical management [3]. An MDT discussion provides a forum wherein specialists can engage in patient selection, match the patient to the appropriate therapy, and consider patients for enrolment in clinical trials. When there is controversy or no clear evidence-based guidance, productive MDTs will reach consensus and can often revisit challenging cases for the continuum of care [4]. In our experience, the establishment of an MDT has been the first step in establishing joint services and this underpins the subsequent outpatient and surgical services.

The core training in obstetrics and gynecology has undergone tremendous change over the last decade. More and more information must be assimilated in a shorter time. The need for competent pelvic surgeons remains clearly important but the integrated structure to achieve this goal remains elusive.

The female urinary tract consists of the kidneys, ureters, bladder, and urethra. The former two organs are exclusively within the remit of the urologist, but there is an overlap between the female urologist and urogynecologist in the management of disorders of the bladder and urethra. Most urologists do not deal with pelvic organ prolapse and concomitant gynecological conditions if any, and this has traditionally been the remit of gynecologist and more latterly of urogynecologist (particularly in the United Kingdom with the advent of special interest and subspecialty training). With this, there has been a greater recognition of what situation is appropriate and more importantly what is not appropriate to be undertaken in isolation.

Recognizing the strengths, limitations of services, and skills required provides the second step to why joint or synchronized clinics may be important and why a joint clinic service delivery model may be the ideal setting to ensure that patients with complex LUTSs receive seamless care and a better patient experience with input from urogynecologists and urologists. This service incorporates specialist urology input along with urogynecology, physiotherapy, and nursing involvement. In a perfect setting, a pain physician and psychologist would also attend periodically for input into selected cases.

The aims of specialized clinic in neurourology, functional urology, and urogynecology are to further investigate the underlying disorder responsible for the urinary symptoms and prevent urinary tract complications. Patients benefit from the joint expertise. In our setting of university teaching hospital, patients who have been seen by the urogynecologists locally or in the surrounding hospitals in the region are seen in these joint clinics. They can have upper or lower urinary tract conditions resistant to the usual treatment regimen offered.

The multidisciplinary joint urology clinic provides

- Diagnostic evaluation and/or treatment
- Coordinated, comprehensive care

- Follow-up and monitoring
- Information, education, and reassurance
- Access to specialty medical care as required

The services offered depend not only on the individual training and expertise of the doctor but also on the resources, availability of equipment, and referral pathways. The urologists perform urinary diversions, urethroplasty, treatment of stones, sacral neuromodulation, and fistula repairs besides managing other LUTSs. In addition, they manage the rapid access hematuria pathways for patients, which incorporate one-stop flexible cystoscopy clinics. The urogynecologist offers concomitant prolapse and incontinence surgery, conservative therapies, as well as simultaneous treatment of any coexistent gynecological problems. This ensures that patient is managed holistically and has a better range of treatment options made available to them.

A joint urology–urogynecology service was set up at the author's hospital to enhance the scope of services provided through a collaborative approach to treatment. It has the following aims:

1. To deliver an excellent experience that exceeds patients' expectations
2. To develop an exceptional organization where people achieve their potential
3. To work with our partners to maintain and develop our service, academic, and research standing
4. To offer an efficient tailored service whereby a patient whose problems overlap both specialties can be seen by both specialists simultaneously allowing a comprehensive management plan
5. To provide a better service for PAG and pediatric urology patients in transition to adult services

The objectives are to offer innovative diagnostic and therapeutic strategies specific to each individual patient's problems and to facilitate the gathering of multiple opinions from various clinical specialists.

Team members include urogynecologist, adult ± adolescent urologist (who attends as required periodically), specialist urology and urogynecology nurses, physiotherapist, and trainees/fellows from urology, urogynecology, and allied professions. The team can access input from other subspecialties (pediatric–adolescent gynecologist) as and when required.

To audit the efficiency of the service, the following outcome data are collected:

- The provision of a multidisciplinary individualized management plan to be shared with the family doctor
- Patient experience/satisfaction through undertaking patient questionnaires—friends and family test [5]
- Objective measures like patient global impression of improvement and disease-specific quality of life questionnaire, e.g., electronic personal assessment questionnaire (ePAQ) pelvic floor [6,7]
- Reduced patient journey—comparison between the length of time and resources spent before (seeing two different specialists in their respective clinics, investigations, and then treatment) and what is now being achieved by consultation in a joint setting

The joint operating sessions generally have patients who benefit from the dual expertise. Some examples include urethral diverticulectomy, vaginal fistula repairs, urethroplasty, pubovaginal sling, neuromodulation, removal or excision of the eroded sling/mesh into the bladder/urethra, and elective abdominal delivery for patients with history of complex reconstructive urological surgeries. There are cases of feminizing genitoplasty, gonadectomy, etc., that are done in conjunction with the pediatric urologist. One might also encounter stigmata or complications from surgeries done in infancy (e.g., girl with CAH who presented with pain after having had clitoral reduction and pull-through vaginoplasty in infancy—see Figure 66.1).

Since its inception, a joint clinic is conducted every 2 months preceded by a MDT meeting where the patients and their management plans are discussed. The data collected prospectively suggest that the joint clinic works well for a reduction in the use of resources (clinic times, waiting times, duplication of investigations, and treatment).

A further review of patient satisfaction was undertaken using the friends and family test [5]; it was apparent that the patients were quite satisfied with the setup and the service provided. When the patients were asked how likely would they recommend this clinic to a friend or family member if they needed similar care or treatment, 10/11 commented that it was extremely likely and 1/11 said it was likely on the 5-point Likert scale ranging from extremely likely to extremely unlikely; 9/11 also thought that everything was done quite well when asked what went well. There were no adverse comments.

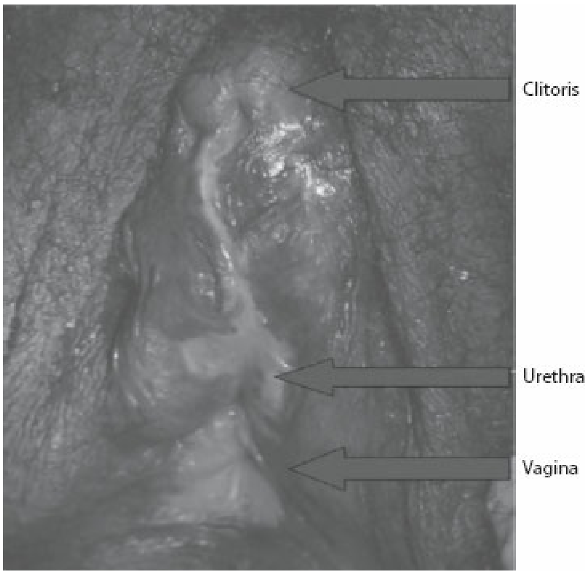

Figure 66.1 Scarring from infant genitoplasty. (Reproduced from Breech LL, Complications of vaginoplasty and clitoroplasty, in Teich S and Caniano DA, eds., *Reoperative Pediatric Surgery*, Totowa, NJ: Humana Press, 2008, pp. 499–514. With permission.)

The standard of care for all patients with urinary problems in the joint clinic is evidence based, guidelines driven, and provided by board-certified or accredited specialists. At the core of the exceptional patient and family experience is a respectful partnership based on enabling them to participate in their plan of care.

JOINT UROLOGY CLINIC FOR SPINA BIFIDA AND EXSTROPHY OF WOMEN

In the care of complex congenital conditions, urological management need to be cohesive to ensure they are effective. All youth must transition from pediatric to adult-centered medical care. This process is especially difficult for youth with special health-care needs. Many young women do not receive the age-appropriate medical care they need and are at risk during this vulnerable time [9]. Young people with chronic illness are significantly more likely than healthy peers to develop emotional difficulties requiring psychological support. The challenge for health services, however, is that the psychological difficulties that young people present with are intimately related to their physical condition rather than being traditional anxiety or depression. Young people worry about their most intimate body parts and about how these parts both look and function.

Table 66.1 Issues Faced by the Young Person and Their Family When Moving from a Family-Based Care Structure to Independent Management

The young person	Transition coincides with other major life changes.
	Greater opportunity to participate in risk-taking behavior.
	Neurodevelopment incomplete; may be perhaps limited by underlying condition.
	May have poor health literacy leading to difficulty implementing treatment information.
	Not likely to prioritize care for medical condition.
	May not be ready to assume responsibility for good urological care.
	Can access many sources of potentially conflicting information.
	Often geographically distant from clinician and medical team.
The family	Parents may no longer had a direct relationship with the clinician.
	Limited recognition of legal status within the doctor–patient relationship.
	Dance of independence with young person.

	Conflict between caregiving and promoting young person's autonomy.
	Advocating for young person versus impeding confidentiality.

For many, these worries only surface as the reality of a future becomes tangible. From mid- to late adolescence, the reality of leaving home and developing independent lives can impact overall adjustment and well-being.

The focus of transitional care is often on the move from one service to another, but it must be underpinned by acknowledging the changing developmental needs of adolescents and young adults. In the transition phase where responsibility for care, interventions, and decisions will shift from parents to the patient, the importance of maintaining attendance and compliance needs emphasis. A young adult will be experiencing many changes: a shift to university or working life, new relationships, and increased personal/fiscal responsibility. It is easy to imagine when someone who is asymptomatic would chose to put a visit to a urologist, gynecologist, or nephrologist far down on their list of priorities (Table 66.1).

We also see patients referred from the pediatric services including the disorders of sexual development (DSD) clinics. The pediatric urologist, endocrinologist, and psychologist provide input into this clinic on a regular basis. The author is a urogynecologist as well as a pediatric adolescent gynecologist who attends the DSD clinics regularly. It provides continuity of care to then review these girls in the joint urology clinics or joint endocrinology clinics as appropriate.

Bladder Care

Bladder reconstruction in childhood creates a lifelong contract between the patient and his/her medical team. Long-term management involves surveillance of functional, symptomatic, and metabolic/renal status [10]. Patients must be under the care of an MDT capable of providing appropriate advice and support in all areas. It is common for issues such as catheterization and bladder emptying to engender resistance in an adolescent patient.

Psychological Care

Female sexual function in DSD like congenital adrenal hyperplasia also generates controversy when surgery is discussed. Outcome data for surgery are lacking. Some significant publications have attempted informing a debate about early surgery, evaluating outcomes, and questioning necessity in infancy and potential benefits (or disadvantages) of early surgery [11,12]. This ultimately relates to potential balance of parental versus patient consent in elective procedures. It is important that decisions surrounding surgery in all these patients regardless of their age are made as part of an MDT to ensure all options and implications have been considered [13].

Adolescent Gynecology

By adolescence and early adulthood, it is important to ensure a conduit for menstrual flow, an introitus and vagina for sexual intercourse, and normal sensation to allow sexual pleasure. It is essential to discuss contraception if sexually active [14,15]. In conditions such as exstrophy, prolapse may be a concern and difficult to treat.

Emptying the bladder with catheterization and emptying the bowels with an enema or suppository will increase the likelihood of “accident-free” sex. After sexual intercourse, the woman should again empty her bladder to decrease the risk of a urinary tract infection. For women who do not catheterize, they could urinate before and after sex. If they still have significant urinary leakage during sex or frequent urinary tract infections, urinary retention should be considered.

Since sexual arousal may not always induce vaginal lubrication, a lubricant may be needed. Other women may have difficulty with intercourse due to physical restrictions from problems with the bones, joints, and/or muscles that affect movement of the hips and legs.

Obstetric Care

Combined clinics also allow a smooth integration into other services, and many young women with spina bifida (SB) and/or hydrocephalus are able to become pregnant.

Changes in the pelvic nerves and muscles mean that pregnancy for women with SB is more challenging than in the general population and should be managed by a team skilled in neurological and urological screening to ensure the pregnancy is not adversely affecting a shunt or their kidneys. The type of delivery depends on multiple physical factors, including sensation level, ability to push with pelvic muscles, size of the pelvis, and flexibility around the hips and knees. The more conducive these factors are to the birthing process, the more likely a vaginal delivery can be achieved.

If it appears that the baby will not be safely delivered via the birth canal, a cesarean section will be recommended. In this case, the urinary tract should be evaluated for reimplantations, diversions, or conduits to make sure they are avoided during the delivery incision. It is best to deliver in an environment experienced in high-risk pregnancies, with urologist available; integration allows these to be planned appropriately and the patients to be familiar with all aspects of their care and the care providers.

Women with bladder exstrophy have a median gestation at delivery of 37 weeks, with 26% at <37 weeks, and generally have cesarean performed with general surgeons or urologist present. In the series reported by Dean et al. [16], 12% of women experienced major birth-related complications such as ureteric transection, fistula, and postpartum hemorrhage. Joint urology clinics provide a good setting to plan these complex deliveries.

CONCLUSION

Fully integrated services with combined MDT reviews have underpinned the development of combined clinics. This has led to an increased collaboration between services and an increase in both patient and health-care professional satisfaction in care provided. In addition, we have noticed a significant improvement in the transitional care of patients leaving children’s services and integrated the care for aspects that have not traditionally been part of pediatric services such as future reproductive health.

67 Multidisciplinary Clinics: Specific Considerations for Elderly Care

Claire Sutton and Philip Toozs-Hobson

INTRODUCTION

Life expectancy has increased over the last 50 years by a decade from 71 to 81 [1]. With this, there are increasing demands placed on health services by the challenges where elderly patients may represent a different set of physiological responses that may require a different approach to management. This trend in life expectancy is likely to continue and the impact of concurrent conditions, and their treatments will increasingly need to be considered as they affect or modify the symptoms or treatments of incontinence. Many patients may age without problem and therefore can be treated in the same way as younger patients, others may develop a number of age-related conditions that impact on each other, and it is this later group that will benefit from a multidisciplinary approach.

In essence, these changes can present patients and their carers with one or both of two challenges: First, continence is a key issue facing older people and as such is often referred to as one of the geriatric giants [2]. Problems with urinary incontinence increase with age and are particularly common in the hospitalized and institutionalized elderly, affecting up to two-thirds of elderly inpatients and those in nursing homes [3,4]. Second, health-care professionals dealing specifically with incontinence are going to need to have a better understanding of the problems specific to aging that represent important cofactors in continence.

Currently, despite the increased prevalence and awareness, many older patients accept incontinence as part of normal aging and as such the complaint is underreported. Unfortunately, it is well recognized that incontinence in older people has far-reaching consequences including social isolation, depression, falls, and pressure sores [5–7]. It is also a common “tipping point” for an individual to move into a care home setting. Carer strain caused by trying to manage relentless incontinence should also not be underestimated [8].

A main drive of caring for the elderly has to be to increase efforts to raise general standards of continence care. This chapter will set out our approach to the multidisciplinary clinic for women with particularly complex multiple problems. It will also outline some of the physiological changes associated with aging. Finally, it will propose a functional approach to the assessment of the potential confounding factors associated with age and basic strategy to dealing with them.

Aims of the Joint Clinic

1. To offer assessment and management advice to patients with incontinence affected by complex comorbidities in a manner acceptable to general practitioners (GP)
2. To offer continence assessment and management to patients with complex medical conditions who have refractory incontinence
3. To have a reductionist approach to polypharmacy
4. To work in partnership with patients, relatives, and health-care professionals providing day-to-day care [9,10] in setting management plans
5. To feed into other health-care resources as appropriate to improve overall treatment/management for patients

Philosophy

The service is commissioned as a multidisciplinary service with additional funding per consultation offset by the reduction in cost from different constituent service appointments. By definition, all women are tertiary referrals as the only route into the clinic is through the care of the elderly service or urogynecology service.

Appointments are deliberately longer and patients are encouraged to attend with relatives or main health-care providers. Consultations take place with both consultants in elderly care and urogynecology, with the support of specialist nurses. All modalities of both services are available to all patients (albeit modified) so that no patient is excluded from any part of the service based on age or disability alone.

Effects of Aging on the Bladder

Through life, the muscle (detrusor) suffers repeated small insults that continually cause damage and replacement of the muscle fibers with collagen. As a result, the bladder becomes stiffer than it was as collagen is less distensible than detrusor, and second, it contracts with less force as there is less muscle. In addition, there are changes to the nerve supply that are discussed in more detail in the following.

Effects of Aging on the Bladder

The combination of these two events, described earlier in small repeated insults over time during events such as pregnancy and childbirth or as a result of infections or distension, results in delayed sensation from the nerve changes and reduced capacity from the increased stiffness. Over time, cumulative small injuries such during pregnancy, infection or distension, cause nerve damage resulting in delayed sensation and reduced capacity increase the possibility of urgency and urgency incontinence occurring. A further effect of the replacement of the muscle fibers with collagen is reduced efficiency of contraction leading to incomplete emptying and a reduction in the functional bladder capacity as a consequence from the failure to empty to completion.

These effects are mirrored in the urethra, where a replacement of muscle with collagen makes the urethra less compliant. This change is seen as a reduction of the maximal urethral closure pressure (potentially increasing risk of “failure” of the sphincter) and second a reduction in distensibility during voiding reducing the urinary flow rate.

Retention

Management of the condition as early as possible and prior to crisis if achievable is important to ensure the best clinical outcome for the woman. Management includes treating allied conditions known to be associated with voiding dysfunction such as constipation and treating conditions that may contribute to complications such as atrophic vaginitis.

Acute retention itself, however, requires catheterization and attempts to improve voiding with cholinergics have proven disappointing.

Specific Effects of Urinary Retention: Physiology and Effects of Distension

The bladder is designed as a compliant organ with small pressure changes for a large change in volume. The bladder spends 99% of its time in a storage function and 1% in voiding. Normal storage pressures run between 0 and 10 mmHg with voiding pressures of up to 25 mmHg and pressures above 10 mmHg are enough to suppress bladder wall perfusion. If this occurs for extended periods of time, the bladder will undergo ischemic changes to the wall.

Such a situation may occur when the bladder is over distended and if it is stretched past the normal elastic limit (plastic distension). The bladder does not immediately recover to contract and empty. If managed immediately and carefully, this effect is almost always reversible.

Effects of Distension Injuries

Short-term injuries may be reversible or result in damage, depending on whether the bladder tissue stretches past the elastic limit into plastic deformity. This in turn causes the bladder to empty inefficiently. Once overdistension raises intravesical pressure beyond 7–10 mmHg, there is a reduction of the oxygen supply [11], resulting in ischemic tissue damage. One consequence of this is an alteration in the nerve supply to the bladder, making the muscle more sensitive to the neurotransmitters [12] in the nerve endings and also a change in the nerve type.

Animal models have demonstrated two effects of ischemia. First is that the bladder loses its ability to empty (although this will usually recover with time) [13–15]. Second, there is also evidence that reperfusion may add a second layer of injury onto the bladder [16], and as a result of this oxidative stress, the ability of the bladder to produce nerve growth factor is reduced after repeated insults [17].

The changes in the bladder's nerve supply leads to an increase in the so-called "nonadrenergic noncholinergic" fibers, otherwise known as the adrenergic fibers [18].

A second insult can occur with reperfusion leading to oxidative stress. This results in the production of nerve growth factor. Repeated insults do reduce this recovery response, and it is probably repeated distensions that create a chronic problem rather than isolated incidents.

The resultant changes mean, with time, that the bladder becomes less compliant with filling (reduced capacity) and also has reduced contractility (poorer emptying).

The result of these episodes is a replacement of the injured detrusor muscle fibers with collagen. Collagen is a structural protein that, depending on the degree of cross-linking having flexible characteristics, is not a muscle fiber and does not demonstrate the same ability to distend in a compliant manner as detrusor fibers or more importantly to contract. The net effect of this is the bladder starts to lose the elasticity required for compliant distension. Second, the loss of muscle leads to a net reduction in contractile force so the ability to empty may reduce.

The second effect is a gradual change in the autonomic nerve supply from the traditional adrenergic and cholinergic fibers of the sympathetic and parasympathetic nervous system to nonadrenergic noncholinergic fibers that use a purinergic transmitter more commonly thought of as secondary messengers such as ATP.

Impact of Voiding Dysfunction

Many women will have suboptimal voiding, but this remains subclinical until symptoms reach the tipping point. The implications for women are threefold. First, symptoms of frequency, urgency, poor stream, double voiding, and nocturia develop related to reduced flow, poor contractility, and delayed/reduced sensation. Second, difficulty with conventional treatment for urgency may occur as the reduction in cholinergic fibers may reduce the effectiveness of anticholinergics, while increasing side effects. This can manifest with elevated postvoid residuals as demonstrated in studies. As such, the introduction of mirabegron, a beta-3 agonist, gives a medication that has different side effect profile and potentially less impact on voiding function.

Finally, problems may develop with sequelae of the poor emptying, such as urinary tract infections (exacerbated by atrophic vaginitis), which can be complicated by upper urinary tract infections and a subsequent effect on renal function.

Precipitating Factors

Situations affecting voiding include concomitant conditions such as constipation and urinary tract infections as well as comorbidities such as diabetes. Various medications can also impact on bladder function such as antihypertensives including rapid-acting diuretics leading to rapid fill and calcium channel antagonists affecting the sensory thresholds. There are also a host of medications with anticholinergic side effects.

Urinary Tract Infection

Urinary tract infections may precipitate retention/voiding difficulties or be sequelae of it. It is important to examine for this and also to send a sample for culture and sensitivity. The importance of microbiology becomes more relevant in chronic conditions and gives evidence as to whether infections are recurrent (as in frequently occurring) or whether they are resistant to clearance, as a result of altered virulence, e.g., as part of a biofilm on a catheter or stone, or by becoming intracellular.

Voiding problems may occur with prolapse and occasionally presents directly as bladder symptoms such as urgency or voiding difficulties but more commonly subclinically, due to the more direct symptoms of a lump/bulge in the vagina. All patients presenting with prolapse should be asked about voiding function prior to surgery. If there is any doubt, then the minimum of a postmicturition residual should be performed, or in more complex cases, urodynamics may be indicated. If poor voiding is identified, then the option of a suprapubic catheter may be considered at the time of surgery being performed for other conditions that may affect mobility.

It is, however, important to recognize that older people are a heterogeneous group, many aging with minimal comorbidities and retaining a good level of independence. Others do not age so successfully and develop multiple conditions, requiring many pharmacological interventions, and are less independent. This latter, frailer group poses a significant challenge, and it is vital to take a holistic approach to their continence assessment and management [19]. It is also important to recognize the common coexistence of the key geriatric conditions, such as incontinence, immobility, falls, and cognitive impairment, as managing one will undoubtedly require recognition and optimization of the others.

EFFECT OF COMORBIDITIES

Aging is commonly associated with the development of multiple comorbidities, many of which may impact on the occurrence and management of incontinence in conjunction with the aging urinary tract. Cardiovascular conditions such as heart failure can lead to fluid overloaded states contributing to nocturnal polyuria and incontinence.

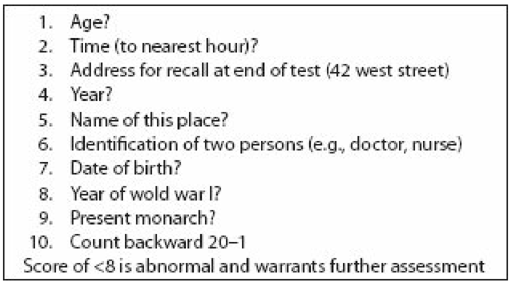
Optimization of the underlying heart failure may, therefore, ameliorate the symptoms. Treatment options for symptomatic relief of excess fluid may paradoxically involve the use of loop diuretics, e.g., furosemide or bumetanide (fast-acting loop diuretics), or slower-acting thiazides that act by inhibiting sodium reabsorption by the distal loop. ACE inhibitors and angiotensin receptor blockers are common first-line therapies with evidence to increase survival. Alcohol is a commonly consumed “social” diuretic that inhibits vasopressin. Diabetes can impact via a variety of mechanisms such as polyuria due to hyperglycemia or functional difficulties such as immobility and ability to self-toilet due to peripheral neuropathy and/or visual impairment from diabetic retinopathy or cataracts. There are a plethora of therapeutic options available to manage diabetes from diet alone to complex regimens including insulin and oral hypoglycemic agents. More recent advances include the use of “gliptins,” e.g., sitagliptin. These drugs block the enzyme that breaks down incretins. Incretins help boost insulin production. Side effects can include nasopharyngitis and so induce a cough worsening stress urinary incontinence (SUI). In the setting of the joint clinic, it would be prudent to assess the control of diabetes by checking a long-acting biomarker such as HbA1c. Elevated levels suggest that management of hyperglycemia is suboptimal, and appropriate diabetes services may need to assess the patient.

Neurological conditions such as stroke, Parkinson’s disease, and spinal cord pathologies can affect continence and are more common in older people, as described in Chapter 51. Incontinence and overactive bladder (OAB) post stroke is common and a poor prognostic marker; further guidance can be found in the Royal College of Physicians (RCP) stroke guidelines. Cognitive issues are common in older people with neurological conditions, and this should be borne in mind when choosing to treat OAB pharmacologically as discussed further in the following text. Musculoskeletal conditions, such as osteoarthritis and rheumatoid arthritis, and previous hip fracture can also impact on functional status and hence continence and are worthy of informal if not formal assessment as a part of the functional review.

Constipation is a common problem in frail older people, especially the hospitalized and institutionalized. This may impact on maintenance of continence by precipitating urinary retention and is often associated with fecal incontinence due to overflow leakage. Continence assessment in older people should, therefore, always include an enquiry into bowel habit, the exclusion of constipation, and usually a digital rectal examination. Enquiry into diet and fluid intake will of course be relevant to constipation and should be considered with bowel care in mind. Encouraging the individual to respond to “the call to stool” and drinking sufficiently may be enough to alleviate mild symptoms. In those with firm stool, a softener should be used such as docusate sodium. Reduced bowel motility usually responds to stimulant laxatives such as Senna or bisacodyl. Impaction is usually ameliorated by way of a strong osmotic laxative such as Laxido. Once the acute constipation is relieved, a bulking agent such as Fybogel should be introduced. Lactulose should generally be avoided and reserved for patients with liver disease. Detection of constipation may be improved with the use of screening questionnaires.

Dementia

This requires particular consideration as it is also often under recognized and/or accepted as part of aging. A continence assessment in an older individual should always include a cognitive screen. A simple question such as the following is a useful start: “have you or your family had any concerns about your memory in the last 12 months?” [20]. If the answer is “yes,” consider completing an abbreviated mental test score (Figure 67.1) [21] and asking the GP to refer to a local memory service for assessment. If the patient is already diagnosed with dementia or dementia is suspected, exploration as to how that impacts on continence is necessary. Cognitive impairment may lead to an unreliable history, reduced fluid intake, or rarely excessive fluid intake. The individual may not consistently remember to take their medication or may become disorientated as to where the toilet is situated, particularly in a novel environment. It may be that the impact is often on the carer rather than the patient; an example is when the patient forgets that he or she has been to the toilet, so having a coping strategy to manage the repeated requests to visit the toilet or conversely putting in a plan for regular toileting to avoid incontinence may be important. Similarly, anticholinergic medication may have an impact on cognitive function [22], and the OAB medication should be chosen with caution. Oxybutynin, in line with National institute of Clinical Excellence (NICE) guidance [23], should be avoided in frail elderly patients including those with cognitive impairment. Agents such as trospium chloride (which is less absorbed across the blood–brain barrier), tolterodine/fesoterodine (bladder specific), or solifenacin/darifenacin (which are more M3 rather than M1 specific) tend to be well tolerated with respect to cognition. Betmiga (being an adrenergic drug avoids muscarinic effects) has evidence supporting a lack of cognitive side effects and is an alternative in patients who either fail first-line therapy or in whom an anticholinergic is contraindicated. Management plans in such cases will inevitably involve support from carers/family and as such they will usually need to be involved in the assessment. Optimizing a continence-friendly environment is also important in patients with dementia. Signage of toilet facilities and contrasting toilet seats can be effective [24].



1. Age?
2. Time (to nearest hour)?
3. Address for recall at end of test (42 west street)
4. Year?
5. Name of this place?
6. Identification of two persons (e.g., doctor, nurse)
7. Date of birth?
8. Year of wold war I?
9. Present monarch?
10. Count backward 20–1

Score of <8 is abnormal and warrants further assessment

POLYPHARMACY

Many older people take multiple medications to treat their many diseases. These may both impact on continence and also need to be considered if continence-specific pharmaceuticals are to be initiated. See Table 67.1.

Table 67.1 Medication and Effect on Continence

Class of drug	Effects on incontinence
Alpha adrenergic agonists, e.g., midodrine, clonidine	Increased smooth muscle tone in urethra urinary retention.
Alpha adrenergic antagonists, e.g., doxazosin	Reduce smooth muscle tone in urethra leading to stress incontinence in women.
Angiotensin-converting enzyme inhibitors, e.g., perindopril, ramipril	Side effects include cough that can exacerbate stress incontinence.
Anticholinergics, e.g., oxybutynin	Retention, incomplete bladder emptying, constipation, cognitive impairment all impact on incontinence.
Calcium channel blockers, e.g., amlodipine, diltiazem, verapamil	Retention, incomplete emptying, constipation contributing to urinary incontinence. Side effects include ankle edema that can lead to nocturnal polyuria.
Cholinesterase inhibitors, e.g., neostigmine, rivastigmine	Increase bladder contractility that may lead to urge incontinence.
Diuretics, e.g., bendroflumethiazide, furosemide	Increased diuresis may precipitate incontinence.

Lithium	Lithium therapy may lead to diabetes insipidus and polyuria. It is also associated with urgency.
Opioid analgesics	Commonly lead to constipation, confusion, and urinary retention that can lead to incontinence.
Psychotropic drugs, e.g., haloperidol	Can lead to sedation, confusion, and impaired mobility impacting on continence.
Selective serotonin reuptake inhibitors, e.g., citalopram, fluoxetine	Increase cholinergic effect hence may lead to incontinence.
Gabapentin, glitazones, NSAIDs	Can cause edema leading to nocturnal polyuria.

Source: DuBeau CE et al., Incontinence in the frail elderly, in *Fourth International Consultation on Incontinence*, 4th ed., July 5–8 2008, Paris, France, 2009.

Aging itself also has an impact on pharmacology. Older people tend to experience more side effects and to suffer more drug interactions. The effects are often underestimated or not recognized as the frail elderly are seldom the focus of pharmaceutical studies due to the number of confounding factors such as comorbidities, and therefore, robust evidence is not always available in this population. It is well recognized, for example, that older patients are more sensitive to anticholinergic side effects (dry mouth, blurred vision, constipation, confusion); it is quite possible that some of this is also a dose effect as relatively higher doses may be required due to the change in nerve supply to the bladder discussed earlier, making the lower dose more refractory. Side effects in general tend to be more common and more severe than in younger, fitter patients, and the mantra of start low and go slow is important to adhere to. The clinician must bear this in mind when treating older patients [25,26].

Pharmacokinetics

Absorption of medication: With aging, GI motility, blood flow, and gastric secretions reduce. Additionally, PPI and antacids are commonly prescribed in the elderly and as a consequence the stomach pH increases [27].

Aging can be associated with a decrease in the functional reserve if multiple organs. As a consequence, they also often take medication for multiple conditions. First-pass metabolism has decreased, and so drugs that are normally rapidly cleared may persist as a result of both the decreased liver mass (with its decreased perfusion) and the increased metabolic activity of multiple medications [28]. Hepatic clearance as a result may decrease by up to 30% and CYP metabolism may also reduce (more so for phase 1 reactions than phase 2). The bioavailability of drugs also may increase. Lipophilic drugs may increase the volume of distribution, with an increased half-life, while water-soluble drugs may do the reverse. As a result, conversely, some lipophilic drugs such as propranolol may have increased first-pass clearance [29].

Finally, with renal function decreasing by up to 50% with age, the excretion of drugs or their metabolites may be reduced. Concurrent hypertension and cardiac disease may place further strain on the renal function.

FUNCTIONAL ASSESSMENT

A comprehensive geriatric assessment of a frail older person presenting with incontinence should always include a history of mobility and ability to get to and use the toilet. Enquiry as to how difficult it is to mobilize and situation of toileting facilities within the domestic situation can be very revealing. An occupational therapist may be required to optimize the ability to use the toilet or may provide an alternative solution or assistive equipment. A physiotherapist may be able to improve mobility allowing the patient to get to the toilet more quickly and safely. Social services may also need to become involved; if it is possible, additional care may be necessary.

CONCLUSION

The increase in life expectancy over the last 50 years has changed how we need to approach medicine. Changes in physiology, comorbidity, and polypharmacy all impact on the delivery of high-quality continence care and need to be considered in the management strategies for elderly patients.

In our experience, the development of joint services has led to better and more appropriate utilization of the services available and increased patient satisfaction.

Surgery for Urinary Incontinence

68 How and Why Incontinence Surgery Works

Mauricio Plata, Nicolas Fernandez, David James Osborn, and Roger R. Dmochowski

INTRODUCTION

Stress urinary incontinence (SUI), as defined by the International Continence Society (ICS), is the involuntary leakage of urine on effort or exertion or on sneezing or coughing [1].

Surgical procedures are considered the most durable treatment for the majority of women with moderate and severe SUI. The history of SUI surgery has seen a broad variety of surgical procedures described based upon the theories regarding the causation of incontinence in vogue during each period of time. Although several risk factors for SUI have been identified such as aging, obesity, pregnancy, and delivery, the pathophysiology of SUI remains poorly understood.

This chapter will review the history of urinary incontinence theories and its relation to the development of surgery through the anatomic landmarks and the proposed mechanisms underneath the procedures performed for SUI.

MECHANISM OF CONTINENCE

The primary principle of any surgical procedure for SUI is to provide urinary continence without disrupting micturition and with an acceptable rate of complications.

Current and past surgical procedures have failed in achieving universal success in urinary continence outcomes. Approximately 30% of the surgical procedures done for SUI are done on patients with recurrent SUI [2]. These failure rates vary depending on the way continence is measured or defined; however, the failure rates are reflective, in part, of the shortcomings in understanding of the pathophysiology of SUI [3].

The physiology of continence depends on central and peripheral mechanisms. There are multiple central input centers such as the cerebral cortex, midbrain, and spinal cord. There are also peripheral control mechanisms that involve not only neuromuscular elements but also myofascial support structures. The coordination of these mechanisms contributes to overall continence status.

Urinary continence during stress maneuvers is maintained by several mechanisms. It is the result of a combination of passive anatomical coaptation and active muscle tone. It depends on the intrinsic properties of the urethra and sphincter, as well as the anatomic support of surrounding tissues. The urethra is normally composed of three layers: the mucosa, spongy vascular submucosa, and the outer muscle layer. The mucosal layer plays an important role due to its coaptation effect upon the urethral lumen. Mucosal secretions increase surface tension, which makes coaptation even more effective. The spongy vascular submucosal layer contributes a compressive effect by vascular perfusion and vasodilatation. Estrogen stimulation loss associated with menopause reduces secretions and vascularization and may contribute to SUI. The outer muscle layer is a very complex mechanism. It is composed of the internal smooth muscle sphincter, which anatomically is not a real sphincter because component fibers are not completely circular. This layer has also longitudinal fibers that emanate from the ureters and trigone and end at the proximal third of the urethra. The external sphincter is composed of striated circular muscle with its thickest part at the middle third of the urethra. The striated sphincter has two different types of fibers: the slow twitch fibers, which create a continuous contraction and keep the urethral lumen closed, and the fast twitch fibers, which contract voluntarily with increases in abdominal pressure.

The anatomic support of the urethra, bladder, and other pelvic organs is provided by the muscles and fascial layers of the pelvic floor. The pelvic diaphragm is composed of the levator ani muscles and coccygeus muscles. The levator ani consists of three muscle layers with a natural hiatus where the vagina and urethra exit the true pelvis. The fascial layers are composed of connective tissue. The endopelvic fascia and arcus tendineus play a critical role in continence and pelvic floor support (Figures 68.1 and 68.2).

Passive transmission of abdominal pressure to the proximal urethra compresses the anterior urethral wall against the posterior urethral wall. Also, the guarding reflex, which results from increasing contraction of the striated muscle of the external urethral sphincter in response to increases in abdominal pressure during Valsalva maneuvers, contributes to continence [4]. Another mechanism that is also additive to continence during stress is the active compression of the urethra against the pubic bone during bladder filling and straining as a consequence of the active tone of the pelvic muscles and their associated ligaments. The role of the urethral smooth muscular sphincter in promoting continence was first described by McGuire in the early 1990s [5]. During videourodynamic studies, urethral mucosal coaptation, either at rest or in the presence of minimal physical stress, was observed to play a key role in the maintenance of continence.

THEORIES OF INCONTINENCE AND ITS RELATION WITH SURGICAL PROCEDURES

Knowledge regarding the pathophysiology of incontinence and its treatment has been in continuous evolution. Since the beginning of the twentieth century, multiple authors have described new concepts in order to better understand this condition.

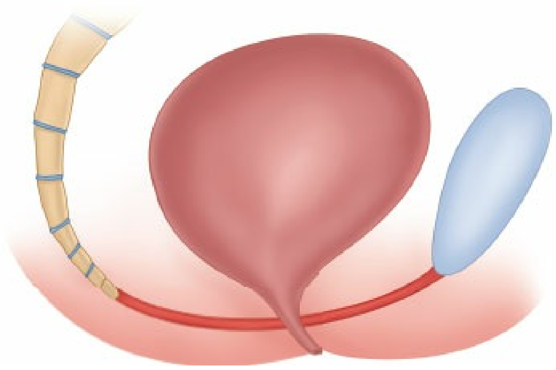

Figure 68.1 Teoria A.

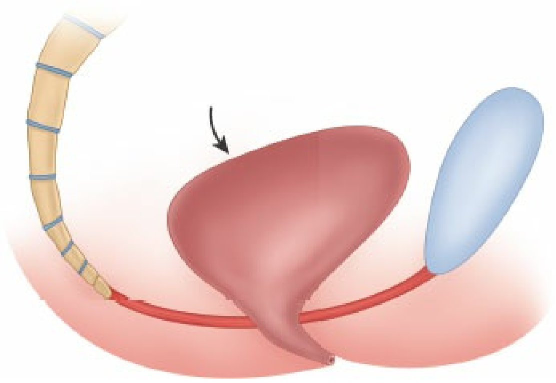

Figure 68.2 Teoria B.

Anatomic Theories

Howard Kelly, a gynecologist at Johns Hopkins, was one of the first authors to describe urethral lumen dysfunction, observed during cystoscopy, as the cause for SUI [6]. Given these findings, he proposed a procedure to narrow the bladder neck in order to improve incontinence—now known as the Kelly plication. He proposed that the incontinence depends not only on the urethra but also on bladder neck compression and that an imbrication of the bladder neck and urethra would reestablish continence.

Bonney, in the early 1920s, described the loss of paraurethral support as a contributing cause of incontinence that resulted from a sudden and abnormal displacement of the urethra and urethrovesical junction immediately inferior to the pubic symphysis [7]. The author described a procedure with the underlying rationale of restoring the urethrovesical junction to a more supported and elevated position above the urogenital diaphragm and providing a restored backboard against which the urethra could be compressed during increases in abdominal pressure. The effectiveness of this depended on the quality of the juxta-urethral supportive structures.

Kennedy demonstrated the contributing importance of the levator ani muscle fibers posterior to the symphysis pubis as supportive elements (15). These results led Aldridge, in 1946, to describe the association between pelvic floor injury after childbirth and urinary incontinence [8]. Damage to either the pelvic floor musculature (levator ani) or pubourethral ligaments was posited to result in descent of the proximal urethra such that the intra-abdominal position of this structure was lost with resultant abdominal pressure transmission directly to the urinary outlet, resulting in urinary incontinence. Repositioning of the urethrovesical junction and proximal urethra into an abdominal position with the aim of equilibrating the transmission of abdominal pressure to the bladder and the urethra became the cornerstone concept for all retropubic procedures such as the Marshall–Marchetti–Krantz (MMK), Burch colposuspension, and later modifications described by Tanagho.

Pressure Transmission Theories

Einhorning proposed, in 1961, that urinary incontinence arose from deficiency of paraurethral support and unequal transmission of abdominal pressures to the urethra and the bladder. He proposed that unequal pressure transmission to the urethra and bladder was a significant contributor to SUI [9]. This theory was supported by subsequent observations by Stevens and Smith [10]. Bump focused on the contribution of urethral pressure to urinary continence and identified that pressure transmission ratios of less than 90% to the proximal urethra had a high sensitivity and positive predictive value for SUI [11].

Urethral Mobility and Sphincteric Theories

Green demonstrated that incontinence was produced when there was a loss of the posterior urethrovesical angle. He divided incontinence into two types according to the angle configuration [12]. Green's theories were further supported using images obtained from chain cystograms.

In some patients who have failed prior incontinence surgery, poor urethral closure function is a frequently associated finding. Some authors have noted that during urethral pressure profilometry, the maximum urethral closure pressure is low and values of <20 cmH_2O are more associated with failure after retropubic procedures [13]. This finding has been termed intrinsic sphincter deficiency (ISD).

ISD is associated with an inability to maintain mucosal coaptation either at rest or in the presence of physical stress. The leak point pressure (LPP) concept was introduced as a simple measure of the degree (or lack thereof) of urethral coaptation. McGuire et al. [5] demonstrated that 76% of those patients with ISD on videourodynamic fluoroscopic visualization had depressed LPPs (<60 cmH_2O). The abdominal LPP (ALPP) has subsequently evolved into one of the primary measures of urethral functional contribution to SUI. The ALPP is defined as the lowest bladder pressure at which leakage occurs during a Valsalva maneuver; however, standardization of measurement has not been universal. Therefore, comparability of this measure across studies is problematic. It has been estimated that up to one-half of patients presenting with incontinence on coughing, sneezing, and other exertional activities actually have a diagnosis of ISD [14].

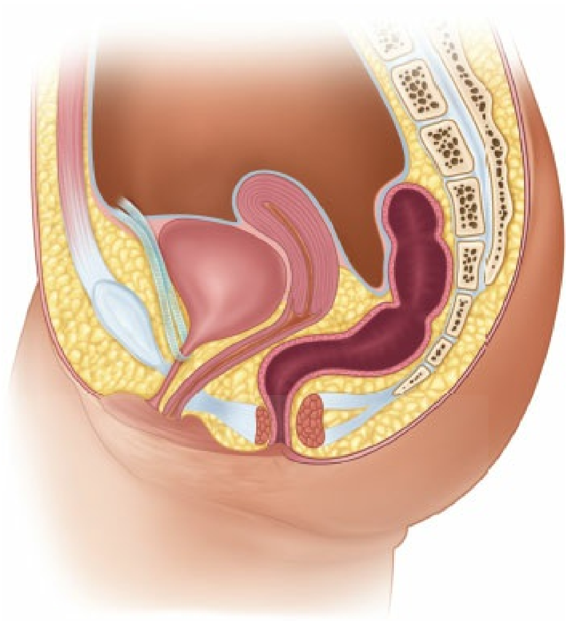

Figure 68.3 Transvaginal tape.

Blaivas demonstrated that genuine SUI caused by anatomical factors or sphincter-related problems such as ISD can be comprehensively diagnosed with videourodynamic studies [15]. He described a classification using videourodynamics, which included anatomical, due to hypermobility of the urethrovesical angle (type 1) or rotational descent of the bladder base (type 2) or due to ISD (type 3). Further classification resulted in the recognition of type IIa incontinence, which was associated with the bladder neck being closed at rest and above the inferior margin of the symphysis pubis. With increased abdominal pressure, the bladder neck and proximal urethra opened and descended more than 2 cm with resultant incontinence. In type IIb, the bladder neck and proximal urethra are displaced more than 2 cm at rest, and the proximal urethra opens with stress and incontinence occurs.

Since midurethral slings have proved to be effective in stress incontinence of either type, this distinction has become less critical, at least between type I and II. With this in mind, a proposal for a new surgical classification simplifies surgical procedures into those that aim to augment urethral closure and those that support or stabilize the bladder neck or urethra [16] (Figure 68.3).

Integral Theory

The description of the “integral theory” substantively impacted the understanding of the continence mechanism and has led to the introduction of the new surgical procedures such as midurethral tapes [17].

This theory holds that pelvic organ prolapse and urinary incontinence are caused by connective tissue laxity in the vagina and supporting pelvic myofascial structures. The vagina has been described as resembling a hammock. Contraction of the pubococcygeus during an increase in intra-abdominal pressure pulls the anterior vaginal wall forward and closes off the urethra. If this system of support is disrupted by laxity in the connective tissues, incontinence ensues. Support of the midurethra is proposed to be the main contributor to continence. Damage to the pubourethral ligaments supporting the urethra, deficient support of the anterior vaginal wall to the midurethra, and weakened function of the pubococcygeal muscles are the described as contributing to SUI [18]. The pubourethral ligaments, inserting at the midurethra, were identified in the early 1960s [19], but their role in functional urethral support was not appreciated until the description of the integral theory.

In 1994, DeLancey proposed the hammock theory. The basis of this theory is that continence depends on the transmission of pressure to the bladder neck and urethra against the rigid support of the pubocervical fascia and anterior vaginal wall. The hammock theory focuses more on causation of SUI than the integral theory [20].

Most recently, a further explained concept has evolved, which is known as the trampoline theory proposed by Daneshgari et al. This theory tries to encompass all previous theories and the multifactorial baseline for incontinence. The trampoline analogy attempts to consolidate the different anatomic and functional elements into a unified concept. Dysfunction of one element of this syncytium may not cause trampoline dysfunction. However, if several elements fail to work properly, functional disorder and urinary incontinence result [21].

SURGICAL PROCEDURES

Details about procedures are not within the scope of this chapter, and extended descriptions of each one of the techniques are described elsewhere in this text. Figure 68.4 shows the timeline for the development of incontinence theories and related procedures.

Urethral Injection Therapy

Urethral coaptation has a contributory effect to urinary continence. The submucosal vascular layer gives a cushion effect that closes the urethral lumen during resting and straining. The mechanism of action of bulking agents is to increase urethral resistance. The use of bulking agents has been described since 1938. Murless et al. used a sclerosing agent to generate scarring and contracture of the vaginal wall in order to improve continence [22].

Another proposed mechanism for bulking effect is that cephalad elongation of the urethra at the bladder neck after bulking results in increased abdominal pressure transmission in the first quarter of the urethra and associated increases in ALPP [23,24].

Agents that have been used for bulking include autologous fat, carbon beads (Durasphere®), calcium hydroxylapatite (Coaptite®), ethylene vinyl alcohol copolymer (Uryx®), glutaraldehyde cross-linked bovine collagen (Contigen®), hyaluronic acid with dextranomer (Zuidex®), porcine dermal implant (Permacol®), polytetrafluoroethylene (Polytef®), and silicon particles (Macroplastique®).

Figure 68.4 Timeline of incontinence theories and surgical procedures.

Why urethral injection works is still completely not understood, but based on the knowledge about urethral opening pressure and coaptation of urethral lumen, the use of bulking agents has been proposed as a therapy to correct SUI. It has been identified that urethral opening pressure at rest after bulking agent injection is unchanged but the opening pressure during stress or Valsalva increases, and this might be the reason why symptomatic improvement occurs. Also, the injection of an agent may increase the sarcomere length of the muscle fibers of the urethral sphincter, creating more power of contraction [25]. The most recent Cochrane review has shown that literature about this technique shows diverse results [26] (Figure 68.5).

Retropubic Suspension

Based upon Einhorning's concepts about pelvic support, pressure transmission forces, and hypermobility, retropubic surgical techniques were developed. The common step among all described procedures is the lifting and fixation of the urethra and bladder neck to the pubic bone or ligaments. The most commonly performed procedures are the MMK and the Burch colposuspension. The MMK was first described in 1949 in a man with urinary incontinence after a perineal prostate resection [27]. The original description for female indications included the placement of vaginal and periurethral sutures. These two were anchored to the periosteum of the symphysis pubis. Reports have shown an 82% success rate. The Burch procedure was first described in 1961 as a modification of the MMK, and it involved the approximation of the periurethral fascia to the Cooper's (iliopectineal) ligament by using three pairs of sutures [28]. The procedure underwent a modification by Tanagho that involved an additional approximation of the anterior vaginal wall to the lateral pelvic walls because overcorrection at the bladder neck did not improve success rates and carried a higher risk of voiding dysfunction [29]. The initial success rate was 100%. The 9-year results showed a 93% success rate but an 8% rate of enterocele. Recently, these procedures have been performed laparoscopically with some early encouraging results, but long-term studies have failed to demonstrate complete success [30–33].

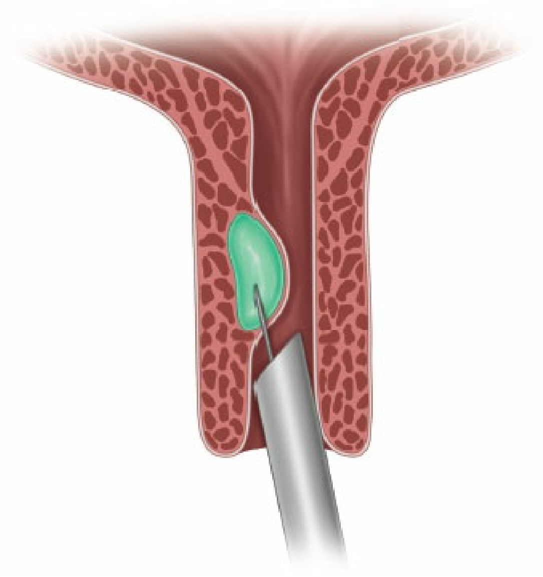

Figure 68.5 Bulking.

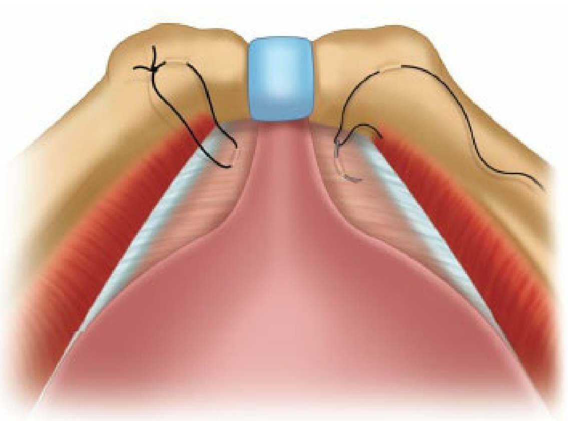

Figure 68.6 Retropubic.

The exact mechanism by which the Burch procedure achieves success is still unknown [34]. Burch originally thought that continence was achieved by the stabilization of the bladder neck and urethra, and MRI studies have shown that descensus of the levator ani muscle and bladder neck is much less in patients with successful results as compared to patients who have failed procedures [35]. With regard to the MMK procedure, how it achieves continence is also unknown. Some propose that Burch colposuspension might show better results because the lateral sutures help to elevate better the levator ani as compared to the more medial sutures of the MMK. For more than 40 years, the Burch colposuspension remained an efficacious and durable procedure in the surgical management of SUI (Figure 68.6).

Transvaginal Suspension

The search for less invasive procedures led to the development of the transvaginal procedures. In 1959, Pereyra described the transvaginal needle suspension. The aim of the procedure was to achieve continence using the same supportive periurethral tissue as the MMK or the Burch colposuspension [36]. Suture fixation stabilized pubocervial fascia to the anterior rectus muscle. A modification proposed by Stamey included the use of an endoscope to verify the correct position of the sutures and synthetic bolters in the vaginal suture to prevent pull-through [37]. Later, Gittes and Loughlin described a similar procedure using blind passage of the ligature carrier without incision of the vagina [38]. Although it is also unknown how the transvaginal procedures exactly work, it is thought that the mechanism is similar to that of the retropubic suspensions. Long-term results of transvaginal suspensions compared to the retropubic procedures are somewhat poor, and the evidence does not support the use of these techniques [39].

Raz in 1981 described his modification to the Pereyra operation. The goal of the procedure was to include the endopelvic fascia for urethral support. The Gittes procedure described in 1987 applied the same technique as Raz however with no vaginal dissection [40].

Pubovaginal Slings

The concept of holding the urethra with a strip of tissue was described more than century ago. Aldridge in 1942 popularized this technique [41]. Some earlier descriptions involved pyramidalis muscle and gracilis muscle. The mechanism of action of the sling procedures runs from passive compression to a dynamic component in which the abdominal musculature plays an important role by pulling upward the sling, giving more resistance to the urethra and bladder neck. McGuire in 1978 used a rectus fascia graft to create an elevation of the bladder neck and give some degree of urethral obstruction during Valsalva maneuvers [42].

The pubovaginal sling procedure consists of a retropubic and transvaginal approach. It does not matter whether the graft is from rectus fascia or fascia lata; the indicated size of the graft tends to be approximately 8 * 2 cm. The area from where the graft will be harvested changes slightly the preparation and patient’s position during surgery. In general, the position is the classic lithotomy position. Once the graft is ready, it is inserted in a “U-shape” way using Stamey needles surrounding the bladder neck with the graft and fixing to the abdominal wall. The common factor among all procedures is that a piece of fascia, graft, or synthetic material is used as a sling that surrounds the urethra in order to increase the support and extrinsic compression at the bladder neck. It is thought that when a Valsalva maneuver occurs, the tension of the sling prevents bladder neck to descend, and urethral wall is fixed and coapts closing the lumen more effectively [41]. The spread of its use was supported by the efficacy in cases with type III incontinence [42] (Figure 68.7).

Tension-Free Vaginal Tapes

This is the latest kind of procedures that have gained the position as the first line of treatment for SUI control given the nature of minimally invasiveness and good long-term results. It was first described by Ulmsten et al. [17]. The initial cure rate was 84% in the first 2 years after surgery. The original description included an incision at the anterior vaginal wall with a submucosal paraurethral dissection immediately behind the symphysis pubis. Then, a polypropylene mesh was introduced on each side of the urethra with a cephalic direction using two pairs of specially designed needles. At the anterior abdominal wall, the needles perforated it and the mesh was then left in place and incisions were closed [43].

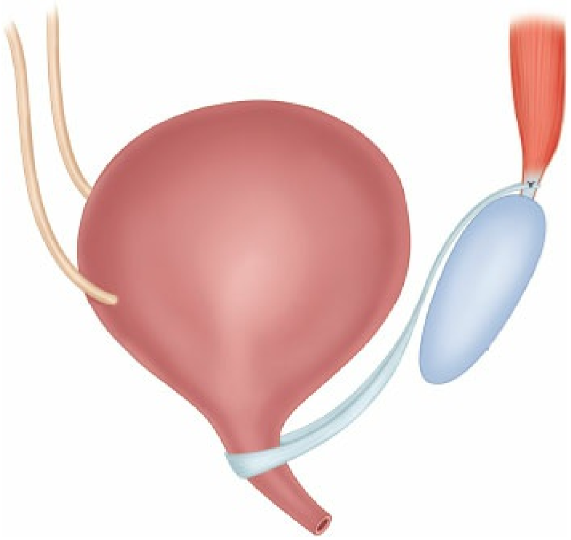

Figure 68.7 Pubovaginal sling.

Several techniques have been described since then, but in general there are two main ones: the transvaginal tape (TVT) and the transobturator tape (TOT) [44]. The difference between these procedures is the direction of vectors. The TVT has a more U-shape kind of vector as oppose to the TOT, which has a more lateral distribution.

All procedures share the same mechanism of action. It is thought that continence is achieved by the support given by the tape, which is focused at the point where the closure transmission forces occur in the midurethra. Since the anterior urethral wall is fixed anteriorly by the pubourethral ligaments and the posterior urethral wall lacks support, real-time imaging has shown that the urethral segment proximal to where the tape is located presents no motion of the posterior urethral wall. This creates a narrowing of the urethral lumen during stress. Surprisingly, the benefit that bladder neck mobility is reduced makes no improvement in continence control [45]. Recent randomized controlled trials have demonstrated equivalence among retropubic and transobturator tension-free slings [46].

CONCLUSIONS

Urinary continence is a complex process, and understanding of this process has evolved over time. The abundance of surgical procedures to correct incontinence, and modifications, thereof, reflects deficiencies in understanding of the pathophysiology of this condition. Currently, urinary continence is considered to be the result of a complex process with contributions from bladder neck, urethral, vascular, neural, and myofascial components. Unfortunately, a comprehensive understanding of the contributions of all of these elements has yet to have evolved. Optimized urethral function (coaptation and vascular flow) with integrity of urethral support and bladder neck smooth muscular function all summate to the continent condition. As of yet, no single procedure addresses all of these components comprehensively, hence the lack of any single procedure providing universal continence to all women undergoing that intervention.

69 Peri- and Postoperative Care

Sushma Srikrishna and Linda Cardozo

INTRODUCTION

Surgical intervention remains the definitive treatment for the majority of women with pelvic floor dysfunction. Although surgical technique is a major factor influencing outcome, other factors such as appropriate patient selection, preoperative investigation and preparation, and postoperative care are also important considerations.

Urinary incontinence and urogenital prolapse are distressing conditions with a significant deleterious impact on quality of life [1,2], but are rarely, if ever, life threatening. Therefore, surgery for these conditions is elective and allows sufficient time for adequate preparation and case selection, which in turn should improve surgical outcome.

Although urogynecological procedures are very rarely associated with surgical mortality, every attempt must be made to minimize intra- and postoperative morbidity.

PREOPERATIVE CONSIDERATIONS

Procedure Selection and Discussion of Alternative Therapies

In the clinical setting, outcome assessment and the definition of "cure" remain poorly defined [3]. Generally, while measures of objective "cure" tend to be favored in the research setting and in the reporting of clinical trials, in everyday clinical practice, more subjective measures of outcome are preferred [4]. The use of patient-reported goals has been described as the fourth dimension in assessing pelvic floor dysfunction [5]. There is also an evidence to suggest that the use of a more individualized qualitative approach may help to tailor patient care and enable clinicians to focus on those specific and often very personal symptoms, which bother patients most. This may ultimately improve patient satisfaction and overall outcome [6]. More recently, global indices that ask a patient to rate the response of her condition to intervention (such as surgery in pelvic organ prolapse) have been used in clinical and research settings. These are much more simple and easy to use, interpret, and ultimately compare across units offering interventions in the management of urogenital dysfunction [7,8].

It is vital that before proceeding to a surgical procedure, a woman should feel that she has had the opportunity to take part in the decision process as this may have a profound influence on her emotional, psychological, and sexual well-being. The information on the possible effects of surgery on physical (with particular regard to bowel and bladder function), hormonal, reproductive, and sexual function should be provided. The full range of therapeutic measures available, expectant, medical, and surgical, should be discussed to allow an informed choice. It is also important to give a realistic view of success rates of individual procedures as well as any possible complications and their likelihood and possible sequelae. This ensures that the woman has realistic expectations regarding her surgery and a clear idea of potential complications, which goes a long way to reducing medicolegal problems.

Use of Alternative Therapies

Surgical intervention should not be undertaken without a comprehensive discussion on available alternative forms of therapy. These options may be particularly relevant for those women unsuitable or unwilling to undergo surgery.

Pelvic floor muscle training (PFMT), with or without electrical stimulation, remains the mainstay of conservative management of urodynamic stress incontinence. The recent National Institute for Clinical Excellence (NICE) guidelines recommend a trial of supervised PFMT of at least 3 months duration as first-line treatment for women with stress or mixed urinary incontinence [9].

Many studies have shown excellent results, although it is clear that supervised PFMT by a dedicated physiotherapist achieves far better results than vague instructions to perform pelvic floor exercises. A recent Cochrane review supports the recommendation that PFMT be included in first-line conservative management programs for women with stress, urge, or mixed urinary incontinence [10], although similar robust evidence is not available to elucidate the role of PFMT in pelvic organ prolapse [11]. A Cochrane review into conservative management of prolapse found some benefit specifically for PFMT as compared to no intervention. The authors concluded that more randomized controlled trials (RCTs) are still needed to look at the different regimens of PFMT, the cost in relation to benefit, and the long-term effects [12]. More recently, a large multicentered RCT establishing the effectiveness of one-to-one individualized PFMT for reducing prolapse symptoms concluded that while there is no doubt that PFMT is effective in the short term, long-term benefits still need to be investigated [13].

As physiotherapy is associated with good success rates and is not associated with significant adverse outcomes, it is recommended that surgical intervention is undertaken only after adequate course of physiotherapy.

Duloxetine, a balanced serotonin and noradrenaline reuptake inhibitors, is the only medical treatment available for stress incontinence. It enhances urethral sphincter activity via a centrally mediated pathway [14]. The evidence reported to date suggests that duloxetine is significantly better than placebo [15], offers an alternative to surgery, and may be complementary to the use of PFMT in the initial management of women with stress incontinence [16]; however, its use is limited by significant side effects such as nausea in a proportion of women [15].

A number of mechanical devices may also be considered in the conservative management of pelvic floor dysfunction. These may be useful in the short term, while women undergo physiotherapy or are on the waiting list for surgery, in those who are unwilling or unfit for surgery and during pregnancy.

Information Leaflets

Research has shown that at any given time, only 10% of verbal information during a consultation is remembered by the patient afterward. This can be substantially increased by the use of written information given to patients during a consultation [17]. Patient information leaflets can be particularly useful if they have been written locally to reflect practice in a particular unit. Written information leaflets can also be reread at leisure by women, allowing them time to consider treatment options and think of any questions that may be addressed at subsequent consultations. In addition, documentation of the use of such leaflets may be particularly useful in medicolegal disputes. Various urogynecology societies such as the British Society of Urogynaecology and the International Urogynecological Association have produced written patient information leaflets on most surgical procedures, which can be easily downloaded and serve as a useful resource.

Preoperative Nurse Assessment

Preoperative counseling by suitably experienced and trained nursing staff may be particularly beneficial. This allows a more comprehensive discussion of any anxieties than is possible on a traditional preoperative ward round. Nursing staff are also appropriately placed to give information about pre- and postoperative care, catheter regimens, drains, dressings, and ward routine. Ideally, the nurse should be one of the team providing care on the ward.

Deferral of Surgery

As most urogynecological surgery is elective, there should be no need for a procedure to be performed under conditions of undue stress. If it is felt that a patient is unsure about the need for surgery or further investigation or counseling is required, then surgery should be deferred. Finally, the surgeon has the ultimate sanction, and if it is felt that an intervention is inappropriate or not in a patient’s best interest, then (after appropriate explanation) it may be wise to refer back to the general practitioner to suggest a further opinion or investigations.

Physical Fitness for Surgery

Weight Loss

There has been extensive research on the association between obesity and increased perioperative morbidity and mortality. Obesity is associated with increased anesthetic complications such as difficult intravenous access, induction, and intubation as well as technical difficulties during surgery. In addition, there is an increase in most postoperative complications such as wound infection, hematoma formation, thromboembolism, and respiratory infection [18]. Therefore, in ideal circumstances, every attempt should be made to encourage obese patients to lose weight preoperatively, including referral to dietician and use of appetite suppressants.

Intercurrent Illness

Before undergoing any surgical procedure, it is essential that a woman is as fit, physically, as possible. The elective nature of most urogynecological procedures allows surgery to be deferred if any intercurrent illness has impaired a woman's general health.

Smoking

In addition to its deleterious effects on health, smoking increases the risk of postoperative problems, such as thromboembolism and postoperative respiratory infections. Also, chronic cough is a factor in the development or recurrence of urogenital prolapse. Most hospitals now offer smoking cessation advice and specialist clinics. Therefore, any patient who is willing to consider giving up smoking should ideally be referred.

Anemia

Anemia increases the risk of postoperative wound infection and delays full recovery. Depending on the level of anemia, the associated symptoms, and the time prior to surgery, this may be corrected by simple oral iron replacement (ferrous sulfate 200 mg daily), antifibrinolytic therapy (tranexamic acid 1 g qds), use of gonadotropin-releasing hormone (GnRH) to suppress menstruation prior to surgery, or preoperative blood transfusion. In addition, GnRH analogues have the advantage of shrinking fibroids, thereby facilitating vaginal hysterectomy or reducing blood loss at abdominal hysterectomy.

Concomitant Medication

The general advice to most patients on regular medication is to continue with these according to their normal routine. The two exceptions to this rule are hormonal or anticoagulant therapy, which may need to be modified prior to surgery.

Complementary or Alternative Medication

The World Health Organization estimates that 80% of the world population uses herbal medicine [19], with an increasing popularity in the use of alternative and complementary therapies. However, it is important to ask specifically for the use of such medications as these are also associated with significant side effects following indiscriminative usage. For example, ginseng may elevate the blood pressure and its excessive use may lead to ginseng abuse syndrome, manifested by diarrhea, skin lesions, CNS stimulation, and interference with homeostasis. Ginseng also potentiates the antiplatelet effect of Coumadin, aspirin, and NSAIDs and taking these drugs with ginseng may pose surgical risks. *Ginkgo biloba*, another traditional herb used in Chinese medicine, is known to decrease platelet aggregation with the anticoagulant warfarin that can interfere with homeostasis. *Ginkgo biloba* will also react with narcotic analgesics causing hypotension [20]. Dong quai (*Angelica sinensis*), used in China for pain and trauma or "female problems," can also interfere with warfarin in high doses. It may potentiate skin cancer or raise blood glucose levels. This is especially dangerous in patients who are diabetic, have heart problems, or are taking anticoagulants. Another popular herb known as licorice root (*Glycyrrhiza glabra*) and its Chinese counterpart (*Glycyrrhiza uralensis*) contain salts of glycyrrhizic acid. This glycoside can intensify platelet aggregation thereby decreasing the Coumadin function [21]. The potential risks associated with the use of alternative medications are listed in Table 69.1 [22].

Hormonal Therapy

Combined oral contraceptive (COC) pills and hormone replacement therapy (HRT) have been implicated as risk factors for postoperative thromboembolism. However, a recent review of literature suggests that the risk of thromboembolism induced by COC or HRT is very small. The increased risk should be compared with the occurrence of undesired pregnancy after discontinuation of COC or the occurrence of climacteric symptoms after discontinuation of HRT. In most cases, these two treatments can be maintained with the use of antithrombotic prophylaxis [23].

Atrophic changes in the vaginal skin can cause difficulty during vaginal reconstructive surgery and compromise postoperative wound healing. Preoperative treatment with topical estrogen for 6 weeks is worthwhile and carries little risk.

Anticoagulants

Most hospitals have local guidelines for the perioperative management of patients on warfarin. Our local guidelines at King's College Hospital are shown in Box 69.1.

Recent evidence, however, weighs heavily toward the continuation of low-dose aspirin (less than 325 mg/day) unless there is a significant bleeding risk associated with the operation [24]. Clopidogrel binds irreversibly to the platelet receptor P2Y12 thereby inhibiting platelet response to both exogenous and endogenous adenosine diphosphate. It is the second most commonly used antiplatelet agent, typically employed both as a substitute for aspirin or as an additional therapy for patients with unstable angina or after coronary stent implantation. If administered for primary prevention in place of aspirin, it can be discontinued 7 days before operation to allow active platelets to be present in the circulation [24].

In the last decade, several novel oral anticoagulants (NOACs) have been assessed in the setting of major orthopedic surgery. These novel agents, dabigatran, rivaroxaban, and apixaban, which have been approved by the European Medicines Agency for the prevention of venous thromboembolism (VTE) after elective hip or knee replacement surgery, have a more predictable anticoagulant effect and a wide therapeutic window, which allow oral administration in fixed dose regimens without the need for routine laboratory monitoring. Moreover, their half-life, shorter than that of the vitamin K antagonists (VKAs) and similar to that of low-molecular-weight heparin (LMWH), represents an additional advantage [25]. At least 1 in 10 Americans receiving outpatient anticoagulant therapy requires interruption of anticoagulation for an invasive procedure annually, and management of these new agents in the perioperative setting is made challenging by difficulty measuring anticoagulant effect and the lack of effective reversal. Surgical planning must account for individual patient risks for bleeding and thrombosis, the type of procedure, and expected drug clearance. Based upon these considerations, a perioperative plan encompassing timing of target specific oral anticoagulant (TSOAC) cessation and resumption, as well as bridging therapy, if needed, can be developed. Perioperative strategies remain largely predicated on extrapolations from pharmacokinetics and expert opinion, though a growing body of literature is providing greater guidance in this important area [26].

For nonemergency surgery, patients should be evaluated by an anesthetist as early as possible to assess an optimal appointment for surgery and bridging strategy. Management of emergency procedures for patients on NOACs requires an interdisciplinary approach. The individual risk for uncontrolled bleeding versus the urgency for surgery needs to be evaluated on an individual basis. The determination of drug serum levels enables a rough estimation of anticoagulant activity. Emergency procedures in coagulopathy due to active bleeding are treated with the unspecific administration of blood products and coagulation factor concentrates [27].

Preoperative Investigations

Preoperative investigations should be tailored to an individual woman's general health and any existing medical problems. The majority of preoperative investigations can be performed on an outpatient basis with the results available for review prior to admission. This allows time for any form of therapy, further investigation, or referral to be made prior to surgery.

Routine preoperative investigations include hematological and biochemical investigations, urinalysis, electrocardiography (ECG), and imaging.

Hematological Investigations

Every woman should have a full blood screen performed to include a hemoglobin count, hematocrit count, white blood cell count and differential, and hemoglobinopathy screen (where appropriate). In addition, the blood should be typed and serum retained for cross matching prior to any surgical procedures that involves a risk of transfusion.

Biochemical Investigations

In healthy women, with no known or suspected underlying medical disorders, these tests may be limited to blood urea and serum creatinine electrolyte levels.

Blood Glucose Control in the Perioperative Period

Uncontrolled blood glucose is associated with a higher incidence of surgical site infections, greater utilization of resources, and increased mortality. Preoperative screening for diabetes in elective surgical patients is not routinely performed. A recent observational cohort study to assess glycosylated hemoglobin screening for elective surgical patients showed that 23% considered very high risk for diabetes and 4% had a provisional diagnosis of diabetes. Many elective surgical patients are therefore at risk for unrecognized postoperative hyperglycemia and associated adverse outcomes. Random blood sugar testing has limited value and HbA1c may be a more appropriate test for the preoperative assessment of diabetic patients [28]. A recent report from the Surgical Care and Outcomes Assessment Program has shown that perioperative hyperglycemia is associated with adverse outcomes in general surgery patients with and without diabetes. However, patients with hyperglycemia who received insulin were at no greater risk than those with normal blood glucose [29].

Table 69.1 Potential Risks of Herbal Medication

Herbal names	**Botanic names**	**Medical uses**	**Potential risks**
Aloe (other names: hsiang-dan, lu-hui)	*Aloe barbadensis/capensis/vera*	Depresses the action potential generation and conduction at neuromuscular junction processes and analgesic and anti-inflammatory effects; increases the collagen content of granulation; tissue contributed to wound healing, sometimes used to treat AIDS, diabetes, asthma, stomach ulcers, immune weakness, evacuation relief, anal fissures after rectoanal surgery, fungal diseases, constipation, colic, and worm infestations	Loss of electrolytes, potassium, and this hypokalemic effect enhanced in conjunction with thiazide diuretics, loop diuretics, licorice, and corticosteroids (increase the action of cardiac glycosides and antiarrhythmic drugs).
Huang-Qi (other names: superior Chinese astragalus)	*Astragalus* species	Used for respiratory infections, immune depression, cancer, heart failure, viral infections, liver disease, and kidney disease; hyperthyroidism, hypertension, insomnia, diabetes, genital herpes, AIDS, and the side effects of chemotherapy	Bleeding when used with other anticoagulant, antiplatelet, or antithrombotic agents. It is incompatible with opiates.
Chinese rhubarb, da-huang	*Rheum palmatum*	Constipation, appetite stimulant, painful teething, delirium, edema, and diarrhea	Electrolyte loss (especially potassium leading to hyperaldosteronisms and enhanced effects of radioactive drugs). Long-term use causes arrhythmias, nephropathies, and bond loss.
Dandelion (other names: lion's tooth, endive)	*Taraxacam offinae/laevigatum*	Dyspeptic conditions, UTIs, liver and gallbladder dysfunctions, loss of appetite, fluid retention, constipation, rheumatism, and diabetes	Not to be used with diuretics, antihypertensive agents and oral hypoglycemic, and mammal- and lactating-related problems.
Ephedra, ma huang (other names: natural ecstasy,	*Ephedra sinica*	Used as CNS stimulant for appetite suppressant, a nasal decongestant, bronchial asthma, joint symptoms, inability to perspire, edema, and pain in the bones	May alter effects of MAO inhibitors, ephedrine, B-blockers, phenothiazines, and Sudafed. Higher dosages result in blood pressure and cardiac rhythm disorders; it has an additive effect

fen-phen)			with caffeine and decongestants and heart rhythm disturbances when used with halothane.
Garlic (other names: da-suan)	*Allium sativum*	For elevated lipid levels, age-related vascular change and arteriosclerosis, inflammatory respiratory conditions, gastrointestinal ailments, diabetes, constipation, and joint pain	Decrease in hematocrit values and plasma viscosity; concomitant use with Coumadin antiplatelet drugs such as aspirin and dipyridamole could increase the effect of bleeding. Risk of bleeding increased with ginkgo or high-dose vitamin E and may increase serum insulin levels.
Ginkgo, *Ginkgo biloba* (other names: xGinkgo)		For organic brain dysfunction intermittent claudicating, vertigo and tinnitus, improving concentration, asthma, hypertonic, erectile dysfunction, and angina pectoris	Spontaneous bleeding due to potent inhibitory effect on platelet-activating factor; care when used with aspirin and other anticoagulant hypertension with thiazide diuretics.
Ginseng (other names: Chinese Red Panax)	*Panax ginseng*/*quinquefolius*	For fatigue and debility, concentration, loss of appetite, cachexia, anxiety, impotence and sterility, neuralgia, and insomnia	Hypoglycemic effects, hypotension resulting with prolonged high-dose ginseng with caffeine, adverse effects with oral hypoglycemic and MAO inhibitors, concomitant use with aspirin, NSAIDs, heparin, and warfarin should be avoided.
Green tea (other names: Chinese matsu-cha)	*Camellia sinensis*	$$$	Vitamin K in green tea interferes with Coumadin, decreases the absorption of alkaline drugs.
Licorice	*Glycyrrhiza glabra*	For cough/bronchitis and gastritis, also used for appendicitis, constipation, increase milk production, micturition, gastric ulcers, headache, sore throat, spleen disorders, dehydration, and chronic fatigue syndrome	Hypokalemia, hypernatremia, edema, hypertension, and cardiac complaints. Additive effect with furosemide and thiazide diuretics. Hypokalemic effects potentiate digitalis toxicity. Severe ventricular tachycardia of the torsade de pointes type resulted with the concomitant use of antiarrhythmic agents and may prolong the half-life of cortical increasing its effectiveness and its side effects.
Papaya	*Carica papaya*	For gastrointestinal digestive complaints, athletic injuries, and herniated vertebral disks	Fibrinolytic effect, tendency to bleed due to interaction with warfarin and increased INR levels.
Prickly ash (other names: toothache tree, stanberry)	*Zanthoxylum americanum*	For toothache, intestinal gas, to promote circulation, and rheumatism	Promote bleeding when used with aspirin or other blood thinners.
Turmeric (other names: jiang huang)	*Curcuma longa*	Dyspeptic complaints and loss of appetite, also cancer, gallstones, intestinal gas osteoarthritis, and rheumatoid arthritis	Alter the action of Coumadin, NSAIDs, and immune system suppressants.
Wild yam (other names:	*Dioscorea villosa*	For rheumatic conditions, gall bladder colic, dysmenorrheal, and cramps	Decrease the anti-inflammatory effect of indomethacin, additive effect with estrogen.

China root)

Box 69.1

Low risk	Atrial fibrillation	Stop warfarin 4 days prior to procedure.	Prophylactic dose of enoxaparin.
	Mitral valve disease Cardiomyopathy	If immobilized, use prophylactic enoxaparin, 40	Restart warfarin post-op if hemostasis is secure. Stop enoxaparin when international normalised ratio (INR) > 2.0.
High risk	Venous or arterial thromboembolism	Stop warfarin 4 days prior to procedure.	Restart intravenous heparin 6 hours post-op if hemostasis is secure (do not give loading dose); check aPTT after 12 hours or subcutaneous enoxaparin treatment dose.
	Mechanical valve replacement	Initiate intravenous heparin or enoxaparin treatment dose when INR < 2.0.	Restart warfarin when appropriate.
		Stop intravenous heparin 3 hours pre-op. If on enoxaparin, withhold dose on day of operation/procedure.	Stop enoxaparin/heparin when INR > 2.0.

Perioperative hyperglycemia has also been associated with increased surgical site infections [SSIs] that can cause significant morbidity and mortality and are potentially preventable. Previous recommendations have been to treat glucose levels above 200 mg/dL. However, a recent Cochrane review found insufficient data to support the routine adoption of strict blood glucose control and insufficient evidence to support strict glycemic control versus conventional management around the time of operation to prevent surgical site infections [30].

Urinalysis

Simple ward urinalysis may be used to exclude a urinary tract infection (UTI) in symptomatic women. The urine should be tested for beta-human chorionic gonadotropin in all women of reproductive age to rule out any possibility of pregnancy.

Electrocardiography

ECG traces are not required for most fit women undergoing surgery but may be required if there is a history of hypertension or cardiac disease. Most anesthetic departments now have guidelines for preoperative ECG recording.

Imaging

The roles of plain and contrast radiology, computed tomography, ultrasonography, and magnetic resonance imaging are discussed in the relevant sections of this book.

All women undergoing surgery for uterovaginal prolapse should have transvaginal ultrasound scan of their pelvis to rule out concomitant pelvic pathology. A recent study has shown that associated gynecological pathology may be found in nearly half of the patients on transvaginal ultrasound scan (TVS), leading to a change in planned management in 2.9% of cases [31]. An intravenous urogram should be performed if an anatomic abnormality suggests that the course of the ureters may be aberrant, if malignancy is suspected or in major prolapse where ureteric obstruction is a possibility.

Pulmonary Assessment

Postoperative pulmonary complications play an important role in the risk for patients undergoing noncardiothoracic surgery. Postoperative pulmonary complications are as prevalent as cardiac complications and contribute similarly to morbidity, mortality, and length of stay. Pulmonary complications may even be more likely than cardiac complications to predict long-term mortality after surgery. The American College of Physicians have published a guideline to provide guidance to clinicians on clinical and laboratory predictors of perioperative pulmonary risk before noncardiothoracic surgery and to evaluate strategies to reduce the perioperative pulmonary risk and focuses on atelectasis, pneumonia, and respiratory failure [32]. This shows that patient-related risk factors, such as chronic obstructive pulmonary disease, age older than 60 years, ASA class of II or higher, functional dependence, and congestive heart failure, increase the risk for postoperative pulmonary complications. In addition, patients undergoing such procedures as prolonged surgery, abdominal surgery, thoracic surgery, neurosurgery, head and neck surgery, vascular surgery, aortic aneurysm repair, and emergency surgery are at higher risk for postoperative pulmonary complications. General anesthesia and serum albumin levels below 35 g/L are also a strong marker of increased risk. Good evidence exists to support risk-reduction strategies, including incentive spirometry and deep breathing exercises, and fair evidence exists to support selective nasogastric tube decompression after abdominal surgery. Fair evidence also suggests that short-acting neuroaxial blockade reduces postoperative pulmonary complications compared with long-acting neuroaxial blockade.

Therefore, routine preoperative chest radiography is now rarely required except in women with cardiac or pulmonary disease. A recent review of literature found that 23.1% of preoperative chest radiographs were abnormal but only 3% had findings clinically important enough to influence management [33]. Most anesthetic departments have guidelines for preoperative chest radiography.

Anesthetic Preassessment

Preoperative assessment by the anesthetist is essential to ensure the safe and smooth running of the operating list. In otherwise fit and healthy women, this is often carried out the evening before surgery, or in the case of day surgery, on the day of surgery, with the notes and results of investigations available. Where major medical problems exist or if there have been previous anesthetic problems such as difficult intubation, anesthetic consultation may be carried out prior to admission. This allows enough time for further investigations and therapy to be instituted prior to surgery.

Informed Consent

Treatment and care should take into account the women's individual needs and preferences. Women should have the opportunity to make informed decisions about their care and treatment. If women do not have the capacity to make decisions, health-care professionals should follow the Department of Health guidelines "Reference guide to consent for examination or treatment" (2001) (available from www.dh.gov.uk). From April 2007, health-care professionals need to follow a code of practice accompanying the Mental Capacity Act.

The treatment, care, and information women are given about it should be culturally appropriate. It should also be accessible to women who have additional needs, such as physical, sensory, or learning disabilities, and to women who do not speak or read English.

Carers and relatives should also be provided with the information and support they need.

Consent is difficult to define succinctly but requires three elements: volition, capacity, and knowledge.

Volition

Volition is based on the principles of self-determination and a respect for individual integrity. This requires that a woman is able to make a decision regarding consent without undue pressure from a third party, either a relative or a member of the medical staff. Legally, a spouse or relative cannot give or withhold consent on a woman's behalf, although it is considered good practice to involve the spouse, particularly where the treatment proposed will affect fertility.

Capacity

Capacity to consent requires that a woman has sufficient intellect to appreciate information discussed prior to giving consent and the mental capacity to appreciate the risks and the consequences of the operation proposed. This is a particularly difficult area when dealing with women whose mental capacity is limited as a result of either intellectual handicap or psychiatric illness. In these situations, it is important to seek additional professional opinion and to seek legal clarification where time allows. The situation when dealing with minors (in the United Kingdom, under 16 years of age) is another delicate area. In general, a parent and the child would be involved in giving informed consent.

However, in the United Kingdom, there is the concept of “Gillick” competency, where a medical practitioner must make a clinical judgment as to whether a minor has sufficient maturity to give informed consent. Although this has clarified the situation in the United Kingdom, it is important that practitioners are aware of the law regarding minors in their own country or state.

Knowledge

A woman should not only have sufficient information concerning the diagnosis and prognosis but also be given sufficient information about alternative treatments and also any reasonably foreseeable adverse effects of the proposed treatment. In general, the information given should conform to that given by a responsible body of medical opinion. Those risks that are commonly associated with a procedure should certainly be discussed; more uncommon complications need not be. It is left to the medical practitioner to decide on an individual patient’s ability or wish to discuss these issues. Usually, any complications occurring more than 1% of the time should be discussed. The need to discuss complications also varies with their potential severity and implications for future health. This means that it is essential to discuss the possibility of a complication that may be relatively remote but which would have a major impact on a woman’s life.

It is essential that the possibility of oophorectomy (for either as a technical necessity or an unforeseen indication) is discussed and documented. The risks of surgical complications such as bladder trauma requiring catheterization and wound infection should also be discussed, as appropriate.

The final decision regarding a woman’s capacity to give consent and her ability to understand the information given is left to the professional judgment of the surgeon.

Most practitioners will use a standard consent form and record any particular information on this. However, the concept of informed consent embraces more than just a signature and so it is important that good records are kept of any discussion and information given prior to informed consent. Finally, consent should only be taken by a medical practitioner capable of performing the procedure.

Last-Minute Preparation

Bowel Preparation

The aim of bowel preparation is twofold: first, to remove bulky intraluminal contents and improve both surgical field visualization and handling of the bowel, and, second, to decrease peritoneal and wound contamination by the intraluminal content in case of inadvertent bowel trauma. However, data to support these aims are conflicting. There is only a single randomized study in the literature addressing bowel preparation before benign gynecological surgery, which suggests no evidence to support its routine use [34].

In our practice at King’s College Hospital, women undergoing pelvic reconstructive surgery, such as colposuspension or vaginal repair, receive a sachet of sodium picosulfate the afternoon before surgery to ensure an empty rectum and a stool softener such as lactulose in the postoperative period to prevent discomfort and straining associated with constipation. Complex surgery such as sacrocolpopexy requires complete access to the sacral promontory or mobilization of the rectum. In these cases, thorough bowel preparation with two sachets of sodium picosulfate the day before surgery ensures an empty rectum.

Thromboprophylaxis

Thromboembolism accounts for around 20% of perioperative hysterectomy deaths [35]. As prophylaxis has been shown to be effective in reducing the risk of thromboembolism, women undergoing gynecologic surgery should be assessed for clinical risk factors and overall risk of thromboembolism and should receive prophylaxis according to the degree of risk [36].

Risk factors may be associated with the disease or surgical procedure (infection, polycythemia, heart failure) or with the patient (age over 37 years, obesity, previous deep vein thrombosis, congenital or acquired thrombophilia, etc.)

Assessment of these risk factors allows patient categorization into low-, medium-, or high-risk categories. The NICE guidelines on reducing the risk of VTE in surgical patients advice the following:

- Patients should be assessed to identify their risk factors for developing VTE (see Box 69.2).

- Health-care professionals should give patients verbal and written information, before surgery, about the risks of VTE and the effectiveness of prophylaxis.
- Inpatients having surgery should be offered thigh-length graduated compression/antiembolism stockings from the time of admission to the hospital unless contraindicated (for example, in patients with established peripheral arterial disease or diabetic neuropathy). If thigh-length stockings are inappropriate for a particular patient for reasons of compliance or fit, knee-length stockings may be used as a suitable alternative.
- The stocking compression profile should be equivalent to the Sigel profile, and approximately 18 mmHg at the ankle, 14 mmHg at the midcalf, and 8 mmHg at the upper thigh.
- Patients using graduated compression/antiembolism stockings should be shown how to wear them correctly by health-care professionals trained in the use of that product. Stocking use should be monitored and assistance provided if they are not being worn correctly.
- Intermittent pneumatic compression or foot impulse devices may be used as alternatives or in addition to graduated compression/antiembolism stockings while surgical patients are in hospital.
- In addition to mechanical prophylaxis, patients at increased risk of VTE because they have individual risk factors (see Box 69.2) should be offered LMWH. Fondaparinux, within its licensed indications, may be used as an alternative to LMWH.

Box 69.2 Patient-Related Risk Factors for Venous Thromboembolism

- Active cancer or cancer treatment
- Active heart or respiratory failure
- Acute medical illness
- Age over 60 years
- Antiphospholipid syndrome
- Behcet’s disease
- Central venous catheter in situ
- Continuous travel of more than 3 hours approximately 4 weeks before or after surgery
- Immobility (for example, paralysis or limb in plaster)
- Inflammatory bowel disease (for example, Crohn’s disease or ulcerative colitis)
- Myeloproliferative diseases
- Nephrotic syndrome
- Obesity (body mass index ≥ 30 kg/m^2)
- Paraproteinemia

- Regional anesthesia reduces the risk of VTE compared with general anesthesia. Its suitability for an individual patient and procedure should be considered, along with the patient’s preferences, in addition to any other planned method of thromboprophylaxis.
- Health-care professionals should encourage patients to mobilize as soon as possible after surgery.

The Royal College of Obstetricians and Gynaecologists (RCOG) has also issued guidelines on the use of thromboprophylaxis in gynecologic surgery [37]. Patients deemed at low risk require attention to hydration and early mobilization only. Those at moderate risk should receive specific prophylaxis with either LMWH (doses varying depending on the heparin used, for example, enoxaparin and tinzaparin) or intermittent pneumatic leg compression. Patients deemed to be at high risk should be given heparin as the aforementioned and in addition be fitted with graduated compression stockings. In patients who are at high risk, a hematologist should also be actively involved in the preoperative thromboprophylactic management.

Prophylactic Antibiotics

Prophylactic antibiotics have been clearly shown to reduce the risk of postoperative wound infection. A reduction in infectious morbidity has been shown with the use of broad spectrum antibiotic prophylaxis in both abdominal and vaginal hysterectomy [38]. Adverse reactions to prophylactic antibiotic regimens are reported rarely, with an incidence of less than 1%. The cost of antibiotic cover is outweighed by the considerable economic savings, most notably the reduction in inpatient stay. The clinical and economic evidence clearly demonstrates the effectiveness of routine preoperative antibiotic prophylaxis. The choice of antibiotic depends upon local guidelines. As the pattern of microbial resistance varies, the most appropriate combination of agents should be selected after consultation with the local microbial service.

However, to reduce bacterial resistance, short courses should be used with routine *first-line* agents. Newer agents should be reserved for the treatment of established antibiotic resistant infections. As the aim of chemoprophylaxis is the prevention rather than the treatment of established infection, regimens used should aim to achieve a high tissue concentration of the chosen antibiotics at the time of surgery when inoculation of the wound occurs. However, as this would mean the administration of intravenous antibiotics some hours prior to surgery, a more practical compromise is to give the first dose at the time of induction of anesthesia, with a further two doses in the first 24 hours postoperatively. It is our practice at King’s to routinely use gentamicin as prophylaxis in any surgery involving urethral instrumentation. In addition, prior to mesh augmentation surgery such as sacrocolpopexy, it is our practice to presoak the mesh in gentamicin solution prior to its use.

MRSA Screening

Over the last 25 years, MRSA has become endemic in many acute hospitals in the United Kingdom.

If a patient does develop an infection, however, different antibiotics have to be used, such as vancomycin, which may not be as effective, has more side effects, and is more expensive than conventional therapy. For these reasons, every effort should be made to prevent the spread of MRSA. The guidance issued in 2008 has also placed a requirement on Trusts to introduce routine MRSA screening for all elective admissions by March 2009. Sufficient time must be allowed between screening and admission, to enable completion of MRSA clearance and rescreening (3 weeks allows time for repeat screening and retreatment, if required). Samples must be taken from the following sites:

1. Nose
2. Throat
3. Groin or perineum
4. Any wounds or open lesions
5. Any line sites

The purpose of the topical eradication protocol is to try to eliminate MRSA skin carriage, reducing the risk of subsequent wound infection and transmission to other patients.

The basic regimens are the following:

1. Chlorhexidine gluconate 4% (Hibiscrub or Hydrex) for body and hand washing daily for 5 days. Alternatively, triclosan 2% (Aquasept) may be used in the event of a patient allergy.
2. Mupirocin 2% nasal ointment (Bactroban Nasal) applied to the inside of the nostrils, using a gloved finger, three times daily for 5 days. Press the nostrils together for a few seconds to thoroughly spread the ointment over the insides of both nostrils.

When MRSA is isolated in an inpatient for the first time, the ward will be contacted by either a microbiology doctor or an infection control nurse. The patient must be isolated in a side room. Gloves and plastic aprons must be worn by all staff for any patient contact. The hands must be decontaminated prior to donning gloves and disposable plastic apron. After contact with patients or patient environment, the gloves and apron must be removed while in the room and disposed of in the clinical waste bin, and the hands must be decontaminated before leaving the room or immediately upon exit.

POSTOPERATIVE CONSIDERATIONS

Immediate Postoperative Care

Normal clinical monitoring of postoperative patients with pulse and blood pressure recording is adequate for most gynecologic patients. In high-risk cases, the hourly urine output is a sensitive measure of peripheral circulation.

Analgesia

Postoperative respiratory complications associated with wound pain may delay recovery [39]. Effective postoperative analgesia can facilitate recovery and reduce morbidity in surgical patients by blunting autonomic, somatic, and endocrine reflexes [40]. Postoperative pain is mediated via nociceptive, inflammatory, and neuropathic mechanisms and varies between individuals and different operative procedures. Multimodal postoperative analgesia addresses both different pain modalities and types of surgery [41]. Multimodal analgesia may also be opioid sparing and reduce opioid-related side effects, thereby facilitating patient recovery and ambulation [42]. Most hospitals usually have a local protocol for postoperative analgesia, which is initiated by the anesthetist. This can then be tailored according to the needs of the individual patient. Postoperative pain management following major abdominal surgery may require the use of patient-controlled analgesia (PCA) or epidural analgesia. A retrospective cohort study showed postoperative pain management was excellent in both groups, although problems related to the delivery of pain control such as prolonged catheterization, increased risk of UTIs, and epidural catheter leaks were more common in the epidural group [43].

Vaginal Pack and Indwelling Catheter Care

Indwelling urinary catheter and vaginal pack has been the standard practice after pelvic floor dysfunction surgery. The catheter is used to allow bladder emptying when natural voiding is difficult or impossible due to the presence of vaginal pack, pain, or soft tissue swelling. The vaginal pack is expected to prevent slight bleeding. The duration of catheterization and vaginal packing has been reduced over the years, but there is no consensus on how to minimize complications, and practice varies.

A recent RCT conducted in our department has shown that there is no evidence to suggest that packing increases pain scores or postoperative morbidity. A trend toward increased hematoma and significant complications was seen in the no-pack group. As vaginal packing does no harm and may be of some benefit, it may be argued that packing should be recommended as routine clinical practice [44].

In a Cochrane study on short-term urinary policies following urogenital surgery in adults, no randomized studies were found comparing the use of urinary catheter versus no urinary catheter in patients following prolapse operations. Seven trials also including other urogenital surgery suggest fewer UTI when the catheter was removed earlier, but no clear pattern in respect of recatheterization [45].

Whether or not to use a particular policy concerning when to remove the urinary catheter and vaginal pack is usually a trade-off between the risks of morbidity (especially infection) and risks of recatheterization. In our practice, both the vaginal pack and indwelling catheter are usually removed in the morning, on the first day after surgery.

Anticipation of Postoperative Voiding Problems

Voiding difficulties may occur acutely following any pelvic surgery and after continence procedures in particular. Acute over distension of the bladder leads to damage of the detrusor syncytium with ischemic damage to the postsynaptic parasympathetic fibers. This may result in insidious deterioration of detrusor function and the onset of voiding dysfunction [46]. Factors that may increase the risk of acute postoperative retention include older patients, long operation time, and high doses of opiate analgesia and PCA, together with large amounts of intravenous fluids [47]. In suspected cases of acute urinary retention, an indwelling urethral catheter should be inserted immediately, although some authors prefer intermittent catheterization [48].

In women judged to be at high risk of retention, suprapubic catheterization may be a preferable option. This can be performed easily at the time of surgery and avoids the need for repeated urethral catheterization. Following removal of a catheter, close monitoring of fluid balance should be continued to prevent recurrent retention.

As voiding difficulties are more common following continence procedures, it is important that women are counseled adequately. The need for suprapubic catheterization, which may occasionally be prolonged as well as the occasional need for clean intermittent self-catheterization (CISC), should be carefully explained preoperatively.

When voiding difficulty is predicted by urodynamic studies, it may be worth teaching CISC prior to surgery. Even though perhaps only a minority of these women will need to self-catheterize, from the psychological standpoint, short-term voiding problems are much better dealt with when they have been anticipated. In other cases, sending patients home with a catheter (urethral or suprapubic) on free drainage for a week or two, followed then by a trial without catheter, is usually a successful strategy.

It is our policy to give patients going home with urethral catheter prophylactic antibiotics to preempt a UTI. A Cochrane review into antibiotic policies for short-term catheter bladder drainage in adults (up to and including 14 days) has also shown that there is evidence that antibiotic prophylaxis compared to giving antibiotics when clinically indicated reduced the rate of symptomatic UTI in female patients with abdominal surgery and a urethral catheter for 24 hours. The evidence indicated that receiving antibiotics during the first three postoperative days or from postoperative day two until catheter removal reduced the rate of bacteriuria and other signs of infection such as pyuria and gram-negative isolates in the patient's urine [49].

Hemorrhage

Intraoperative Hemorrhage

Significant hemorrhage is very rare following urogynecological surgery. In the event of massive hemorrhage, it is important to monitor the coagulation status of the patient repeatedly during resuscitation to diagnose the onset of a consumptive coagulopathy. If an abnormality develops, expert advice from a hematologist should be sought. In cases of massive intraoperative bleeding complicated by coagulopathy, it may be very difficult to achieve hemostasis. In such situations, the use of pelvic packs for 48 hours may be the only option, although this necessitates a second laparotomy to remove the packs. Occasionally, embolization of actively bleeding blood vessels using interventional radiology techniques may be an effective alternative to surgery.

Postoperative Hemorrhage

The management of hemorrhage in the immediate postoperative period may be approached in several ways. In broad terms, bleeding may be classified as either localized or generalized.

If localized, the bleeding is usually related to the operative site and/or the wound. Occasionally, the bleeding may be at a point removed from both these areas, for example, gastrointestinal hemorrhage from a stress-related gastric erosion. Bleeding from the wound site is usually indicative of a mechanical problem or a local sepsis. Generalized bleeding may reflect a coagulation disorder and may be manifested by the oozing of fresh and unclotted blood from wound edges and with bleeding from sites of cannula insertion.

Most cases of reactionary (and primary) hemorrhage are from a poorly ligated vessel or one that has been missed and are not secondary to any coagulation disorder. The bleeding point may go unnoticed during the operation if there is any hypotension and makes itself known only when the patient's circulating volume and blood pressure have been restored to normal. The bleeding in secondary hemorrhage is due to erosion of a vessel from spreading infection. Secondary hemorrhage is most often seen when a heavily contaminated wound is closed primarily and can usually be prevented by adopting the principle of delayed wound closure.

The approach to management will depend on the overall condition of the patient and the assessment of the type of bleed. A stable patient with a localized blood-soaked dressing will be managed differently from a hypotensive patient with 2 L of fresh blood in an abdominal drain, who in turn will be managed differently from a patient with a low platelet count and fresh blood oozing from all raw areas.

In the first case, the tendency might be to apply another dressing in an attempt to achieve control by pressure. A more positive approach is to remove the dressing and inspect the wound. In most instances, a single bleeding point can be identified and controlled. In the next case, the patient has a major bleed and this is probably from a bleeding vessel within the operative site. Return to the operating room and formal re-exploration must be seriously considered. In the third case, the prime problem is one of an anticoagulation defect requiring urgent correction.

The diagnosis of postoperative hemorrhage is a clinical one, based on the knowledge of the surgical procedure, the postoperative progress, and an assessment of the patient's vital signs. The blood loss may not always be visible and could be concealed at the operative site or within the digestive tract. The treatment of postoperative hemorrhage depends on the severity of the bleed and the underlying cause. Hypovolemia and circulatory failure will demand urgent fluid replacement and consideration of the likely cause and site of bleeding. Careful consideration must be given to control of localized hemorrhage and whether reoperation is warranted. Decision regarding re-exploration may be difficult and the advice and help of the most experienced person should be sought. As a general rule, the sooner after the surgery the bleeding presents, the more likely that re-exploration will identify a single obvious bleeding vessel, whereas delayed bleeding is usually due to infection.

Infection

It is uncommon for women undergoing routine urogynecological procedures to develop infections in the immediate postoperative period, if they have been given prophylactic antibiotics as outlined previously. A recent large study looking at morbidity outcomes in nearly 80 thousand hysterectomies done for benign indications showed that the odds of postprocedural infections (excluding UTI) were generally lower for women who had vaginal hysterectomies. The odds of UTIs were higher in women undergoing hysterectomy for leiomyoma, genital prolapse, and pelvic inflammatory disease [50]. Early detection and vigorous treatment in accordance with hospital protocols is vital in the management of any postoperative infection.

Bowels

Routine procedures such as hysterectomy done for benign indications are not associated with significant alteration in bowel function in the postoperative period. In a recent prospective cohort study, neither abdominal nor vaginal hysterectomy has been associated with constipation, aggravation of constipation, or rectal emptying difficulties 3 years after surgery [51]. In our practice, we routinely advise a mild suppository on the second postoperative day to ensure normal bowel function prior to discharge. All patients with a history of constipation are advised on regular laxatives to ensure regular bowel movements. We would recommend the use of Senokot or Movicol rather than Fybogel or Lactulose.

Removal of Suture and Pelvic Drains

Most urogynecological surgery is performed vaginally using absorbable sutures. In the minority of women who undergo abdominal surgery, removal of skin sutures is usually arranged on the fourth to sixth postoperative day if nonabsorbable sutures have been used. Pelvic drains may be used in conjunction with surgery; the general rule is to remove these when they are no longer draining significant amounts of fluid, most commonly the morning after the procedure.

Mobilization

Early postoperative mobilization is beneficial in the prevention of VTE [52] as well as postoperative ileus [53].

Follow-Up

It is our routine practice to arrange follow-up appointments for all patients at 6 weeks postoperatively as well as to arrange postoperative urodynamic assessment at the 6 months postoperative visit for all patients who have undergone continence surgery.

CONCLUSION

Adequate preparation for surgery has an important role in ensuring an optimal outcome and reducing morbidity. The elective nature of most urogynecologic surgery allows time to ensure that all women are well prepared, both psychologically and physically, before undergoing the chosen operation.

70 Traditional Surgery and Other Historical Procedures for Stress Incontinence

Malcolm Lucas, Elizabeth Timbrook Brown, and Roger R. Dmochowski

INTRODUCTION

The surgical management of stress incontinence has traditionally been based on basic principles with slight modifications accompanied by the occasional advancement by a handful of individuals, leading to dramatic changes in practice.

Our concept of what is historical or obsolete can change rapidly. In part, this reflects the emergence of new and compelling clinical or economic evidence [1,2], but there is no doubt that fashion also plays its part. Surgeons are easily seduced by new technology, and a woman's perception of whether a procedure is newer or older affects the choices she makes [3]. The regulation of new techniques, in most countries, is almost absent, and so the commercial pressure on manufacturers to exploit the market is irresistible. Innovative techniques that facilitate rapid turnover and minimal hospital time are embraced by healthcare providers long before anything is known about the long-term outcomes or risks.

These have been powerful influences and so, once popular operations such as autologous fascial slings, biological grafts, needle suspensions, and anterior colporrhaphy (AC), as well as lesser known operations, find themselves relegated to the historical section of this book. This is in line with the current guidelines from the National Institute for Health and Clinical Excellence (NICE) [2], the International Consultation on Incontinence (ICI) [4], and the American Urological Association (AUA) [5]. However, recent concerns by the Food and Drug Administration (FDA) regarding mesh have presented surgeons with a unique challenge as patients may approach surgeries involving mesh with trepidation, suggesting that these "historical" procedures may become relevant yet again. Thus, a careful review of these techniques remains a valid study, partly as it provides a backdrop and illustration of the changing thought processes that have emerged over the years, but also as a yardstick against which newer techniques can be compared.

AIM OF SURGERY

The aim of any operation for stress incontinence is to achieve balance between continence and voiding as simply and as durably as possible without serious operative complication such as the creation of obstruction or urgency.

It has always been understood that by simply obstructing the urethra, one could render a woman continent. Early slings addressed the problem in this way with an acceptance that obstruction could result in urinary retention.

A long-held belief about the etiology of stress incontinence declared that it was necessary to lift the urethrovesical junction and hence proximal urethra into an intra-abdominal position, in order that during moments of increased pressure, that pressure could be equally conveyed to the bladder and urethra with no resultant leakage. This was the basis of retropubic suspensions such as the Marshall–Marchetti–Krantz (MMK) and Burch colposuspension as well as subsequent needle suspensions.

Blaivas popularized a classification of stress incontinence in which the cause was seen as either anatomical, due to hypermobility of the urethrovesical angle (type 1) or rotational descent of the bladder base (type 2), or alternatively due to intrinsic sphincter deficiency (ISD) (type 3) [6]. Diagnosis along these lines made urodynamics—even video urodynamics essential. It followed then that where hypermobility was identified that procedures to elevate the bladder neck were used, and where ISD was shown, an obstructing procedure would be chosen. The current prevalent view—based on DeLancey's theories [7]—holds that there is a passive component of compression against a "backboard" created by the normal supporting structures of the urethra and bladder base, together with an active sphincteric component, which provide continence. However, since midurethral slings have proved effective in stress incontinence of either type, this distinction has become less critical, at least at the time of primary surgery.

INDIVIDUAL CHOICES

The need to treat each patient individually is obvious. There are many factors that, intuitively, one feels must have an impact on surgery and its outcomes. However, the evidence to support the contributory significance of these “confounding variables” is generally poor or absent. The subject has been extensively reviewed as part of the work of the ICI working group on surgery for women with incontinence [8].

Age, parity, estrogenization, and body mass index are all factors that might alter tissue quality and laxity. Previous surgery will usually have produced scarring with resultant tethering or fixity, possibly have interfered with normal sensory innervation, and possibly have altered sphincter function and pressure transmission in some way. The coexistence of varying degrees of hypermobility and descent of the vagina, the bladder base, and its fascial supports, and how much this bothers the patient, will influence the choice of surgery. While there is no evidence that coexistent medical conditions affect results of stress incontinence surgery specifically, surgeons tend to think that coughing and straining at stool are likely to adversely affect mechanical repairs and that comorbidities that are known to affect healing, such as diabetes, will also have a negative impact.

The psychological profile, expectations, and motivation of women will differ greatly, and this may significantly alter perceptions of outcome, even when the degree of urinary control experienced by two individuals is the same.

All of these issues require good-quality research studies to establish their importance. How much we should take them into account when choosing operations or interpreting what we read is unclear, while the ideal operation would work just as effectively regardless of these factors.

INTERPRETING THE LITERATURE

The randomized controlled trial (RCT) in surgery remains something of a rarity. Two reviews in the 1990s found that the total number of women in the world who had ever been recruited into a randomized trial for stress incontinence surgery was less than 600 in only seven studies [9,10]. By 2006, there were 53 RCTs and over 5000 women had been treated in this context [2]. However, the quality of that evidence remained poor, and there is probably only one adequately powered study to pass the demanding test set by CONSORT [11] in the field of stress incontinence research [12]. Even in recent years few RCTs have been devoted to these procedures, many of which are now considered obsolete.

There are other problems with the literature. The lack of consistency of outcome measures makes comparison of evidence dangerous. Many authors refer to subjective and objective cure rates, but these terms are rarely defined. There are degrees of objectivity, and it is debatable whether a quality-of-life questionnaire is truly objective unless the context in which it is applied is both independent and carefully controlled [13]. Some papers report complications and others do not. In some cases, outcomes have been recorded by “chart review” and in others by independent assessors using validated tools.

Most innovators are constantly changing their surgical practice in search of refinements, which make procedures easier, quicker, cheaper, less morbid, or more effective. Thus, it is rare for the original technique described to remain constant over the years that the surgeon performs it, and one must question the extent to which, when operations are lumped together into a series, the procedure was truly the same for every woman. Surgeons remain reluctant to report poor outcomes, and publication bias always favors the positive message.

One critical issue is how nonattenders and dropouts are reported. Most studies ignore them and offer their results as a proportion of patients who were available for follow-up. However, this makes unsafe assumptions about nonattenders, which may not be justified. The UK tension-free vaginal tape (TVT) versus Burch colposuspension trial [1] illustrated this point very clearly—in the same study, success could vary from less than 30% to over 90% depending on the outcome definition and which population was analyzed. We have observed the same phenomenon in the trial of two lengths of autologous fascial sling [14].

An interesting debate is emerging about the relative value of RCTs on the one hand and large national or international registries on the other. The RCT asserts a rigor to the collection and reporting of data, but sanitizes recruitment and disallows the kind of individual decision making and modification of approach that occurs with patients in normal practice. This results in poor external validity. The large-scale registry, on the other hand, can include all women and all surgeons [15].

For the purpose of this review, evidence has been presented as the original author intended. In most cases, this is a “per protocol” analysis in which dropouts are disregarded. A few studies report outcomes as “intention to treat,” and this is often what accounts for apparently poorer results. What matters most to women who are about to undergo surgery is what happens in the hands of their surgeon, and for this reason, surgeons should audit their own outcomes rigorously and compare their performance with others by participating in larger registries.

ANTERIOR COLPORRHAPHY

The operation (AC) aims to restore a normal anatomical position of the anterior vaginal wall by means of plication sutures to the endopelvic fascial layers between the bladder base and vaginal skin. These structures, under normal conditions, provide support to the bladder base, urethra, and entire sphincter mechanism. The thinking behind this was to restore the urethrovesical junction to an elevated position above the urogenital diaphragm and to provide a restored backboard against which the urethra could be compressed during coughing, straining, etc. The obvious flaw in this proposal is that success will depend on the integrity of intrinsically weak and damaged tissues. Ultimate failure therefore seems inevitable unless the scar tissue, which replaces the weakened fascia, will have greater strength than normal fascia. Many authors have added a sling to colporrhaphy to support the urethra—this makes interpretation of the evidence from these studies difficult to interpret [16].

The operation begins with infiltration of the anterior vaginal wall to perform hydrodissection of the vesicovaginal plane. A longitudinal incision is made from the urethral meatus to the vaginal apex and held apart using Allis forceps.

Lateral dissection of this avascular plane continues laterally sufficiently to expose the hernial defect in the endopelvic fascia, and, in women with significant prolapse, this may be extended as far laterally as the pubic ramus to fully expose the bladder base and urethra. The next step is to place “buttressing sutures” to the fascia on either side of the urethrovesical angle or bladder neck and one or two additional similar sutures to the paraurethral tissues—these sutures are tied in the midline, creating a shelf or hammock upon which the bladder neck and urethra will then be supported. Any additional prolapsing of the bladder base, or cystocele, is then reduced by means of additional plicating sutures or alternatively by means of a purse-string suture—in effect a reduction of the hernia with consequent cranial distortion of the bladder neck. The judgment in this procedure is in providing enough support to the previously prolapsed structures while avoiding overtightening and consequent vaginal narrowing. Excess vaginal epithelium is then sometimes trimmed away though not all surgeons would do this because of the attendant risk that removal of the epithelium could cause a stenosing ring in the midvagina. All such narrowing can be a cause of postoperative dyspareunia.

In execution, if not in intent, this procedure was in effect a hernia repair. While this made some sense if the underlying defect constituted a central defect of the paravaginal fascia, many anterior wall defects result not so much from central attenuation of this layer but from loss of attachment laterally to the arcus tendineus fascia pelvis (ATFP). In these patients, it is possible for the central layer of vesicovaginal fascia to remain intact. The failure to make this distinction may lie behind some of the poor reported results for AC.

There is arguably still a place for anterior repair for the treatment of pure anterior wall prolapse or where stress incontinence is only a minor part of this problem. It can also be used in conjunction with another procedure such as a sling simply to control the cystocele element when both coexist.

A great deal of the literature on AC relates to its use in the repair of prolapse, and relatively few studies address the question of how it performs as a stress incontinence operation. This review focuses only on the latter (Table 70.1). Seven RCTs were identified, four of which compared AC to Burch colposuspension [17–20] and one which compared it to a four-corner Raz suspension [21]. A total of 180 women have been treated by AC in an RCT compared to 195 Burch. Objective cure ranges from 69% at 12 months to 37% at 5 years compared to 87% and 82% for Burch. Deterioration with time does seem to be a problem [18,21]. Two other studies listed compare AC to the newer transvaginal mesh procedures, though this is predominantly covered in another chapter. Both of these studies showed superior results at 12- and 24-month follow-up when compared to AC alone [22,23].

Seven separate cohort studies with follow-up in excess of 5 years were found, which reported comparisons with Burch [24–26] and MMK [27–30]. In these studies, the subjective cures for AC ranged from just 21% to 50%.

It does seem that the long-term outcomes for AC as a treatment for stress incontinence are poor, by any standards.

PARAVAGINAL REPAIR (PVR)

In women in whom there is anterior wall descent but maintenance of normal rugosity of the vaginal epithelium, there is usually an underlying defect of the paravaginal fascia. That is to say that the normal attachment of the endopelvic fascia to the ATFP has become disrupted, and very often in these women, the layer of the fascia in between the bladder base and vaginal epithelium remains intact. It is logical in such women to attempt PVR. The operation can be performed either transvaginally, retropubically, or laparoscopically. The latter two approaches will be described in other sections of this book. Paravaginal defect repair is more commonly reported in association with other techniques such as sling or Burch, so it is difficult to establish how much effect this procedure has on the control of stress incontinence.

When repaired through a vaginal approach, the operation commences as for an AC, but the dissection of the vesicovaginal plane continues laterally to the pubic rami and into the space behind the pubic ramus. In a normal woman, the thick layer of the endopelvic fascia will prevent further progress at this point, but when this layer has failed, dissection will continue into the retropubic space without difficulty.

Laterally, along the surface of obturator internus muscle runs the ATFP from the pubic symphysis anteriorly to the ischial spine laterally and can usually be easily palpated. A series of plicating sutures are then applied, which incorporate three bites each—the lateral structure of ATFP or obturator fascia, the medial structure of endopelvic fascia as it lies under the bladder base or paraurethral tissues, and thirdly the vaginal muscularis itself. A row of sutures is placed on each side and then carefully tied so that accurate tissue apposition is achieved without distorting the positions of the bladder neck or vaginal vault. As the sutures are tied, the anterior wall descent should be seen to reduce itself back toward a normal anatomical position. When performed from a retropubic approach, the same three layers of tissue are exposed and approximated using sutures placed from above. It has to be said that exposure is much easier through the retropubic or laparoscopic approach than through the vagina.

Scotti et al. [31] did a cadaver study in which he identified the strongest attachment points for this procedure—namely, the ischial periosteum and the obturator membrane—using these fixation points as the basis for plication of the more medial structures. His series of 36 women with stress incontinence achieved a 94% subjective cure rate at a median follow-up of 39 months.

The PVR would be a rare procedure to correct isolated stress urinary incontinence (SUI) and would only be potentially beneficial in the setting of preoperative hypermobility with an obvious lateral vaginal defect. One of the difficulties with interpreting any literature on this subject is the uncertainty about whether case selection followed these principles.

Once again, PVR has been reported more commonly in association with other suspensory procedures, and it is impossible from these studies to ascertain what contribution has been made by the PVR alone.

Only one RCT exists for PVR as a stress incontinence operation compared to Burch [32]. However, the length of follow-up was not reported, and “objective cure” was said to be 61% compared to 100% for Burch; thus, little confidence can be placed in this study.

In three case series, the subjective cure rate at a minimum of 12 months ranges from 43% to 94% [31,33,34]. In conclusion, there is insufficient evidence to support the widespread use of PVR alone for stress incontinence control. For urogenital prolapse, see further Section 8.

NEEDLE SUSPENSIONS

In the late 1950s, the most common operations performed for stress incontinence were the MMK and the AC. Pereyra felt that failure was less likely to occur if the suspensory sutures could be supported by the abdominal fascia rather than the periosteum of the pubic bone [35]. In this way, he believed that contraction of the rectus muscle would provide dynamic support of the bladder neck. He designed a special angulated trocar and cannula through which stainless steel wires could be inserted from a suprapubic stab incision to emerge lateral to the bladder neck about an inch apart (Figure 70.1). These wires in turn were tied over the rectus sheath to provide elevation of the bladder neck. A series of diathermy burns made with a pointed diathermy probe pushed through the vaginal skin lateral to the urethra was used to induce paraurethral scarring so that the wires could elevate fibrous tissue rather than cutting through. In his first 31 cases. there were apparently just three failures.

As is usual with all innovative procedures, other surgeons (including himself) immediately adapted and modified his ideas. However, it was not until the late 1970s and early 1980s that needle suspensions became highly popular. The essence of Pereyra's procedure—placement of nonabsorbable sutures through the retropubic space by means of a long needle/suture carrier, fixation at one end to paraurethral tissues, and at the other end fixation to the rectus fascia (RF)—was the basis of every subsequent modification of the technique.

Two major modifications led to the popularization of these techniques.

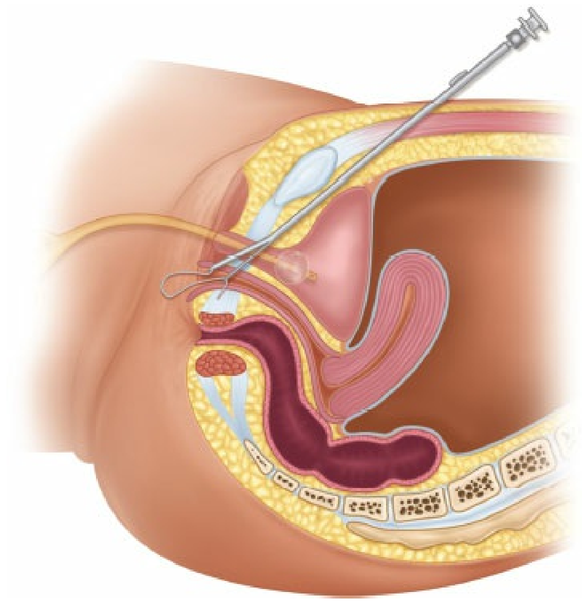

Figure 70.1 Pereyra operation. Illustration showing the angled trocar and needle used by Pereyra to load a stainless steel suture with a measured thickness of paraurethral tissue in between to facilitate elevation.

Stamey

In 1973, Tom Stamey described the use of the cystoscope to standardize the procedure [36]. The cystoscope was used both to check suture placement and also to adjust the tension so that appropriate closure of the bladder neck could be achieved.

Stamey's operation is performed in the lithotomy position using a weighted vaginal speculum. Having emptied the bladder with catheter placement and identified, by palpation, the position of the bladder neck, a T incision is made on the anterior vaginal wall to expose the urethrovesical angle. Many other surgeons, of course, adapted this, and incisions of all shapes have been used to expose the area

(Figure 70.2).

With minimal dissection of the vaginal wall away from the pubocervical fascia, a small pocket is created in the paraurethral tissues adjacent to and approx. 1 cm lateral to the bladder neck. Through two small suprapubic stab incisions, a single pronged needle (either straight or bent at 30°) is introduced, puncturing the rectus sheath and then downward through the retropubic space to emerge onto the tip of the surgeon's finger in the previously created pocket. The needle is threaded with a nonabsorbable suture and withdrawn. A 1 cm length of Dacron arterial graft is threaded onto the suture. A second needle passage is then made, about 1 cm from the first toward the same pocket and the remaining end of the suture pulled cephalad to emerge through the stab incision. On pulling up the sutures, the Dacron cuff settles into the pocket and pulls up the bladder neck on that side. This procedure is repeated on the other side.

At this point, the cystoscope is passed, and by pulling upward on the sutures, the surgeon can confirm that they are positioned correctly at the level of the bladder neck, that they are not passing through the bladder, and the correct amount of tension for tying the suture over the rectus sheath can be selected by observing the point at which the proximal urethral mucosa begins to oppose. Initial voiding difficulty was the norm, so the routine was to place a suprapubic catheter postoperatively and undertake an initial trial of voiding after say 48 hours.

This operation was devised at a time when the prevailing thinking was still that one should achieve elevation of the bladder neck, and this implied that tension need be applied.

All subsequent minimally invasive procedures for incontinence have applied this principle of midoperative cystoscopy until the advent of the obturator tape in recent years.

Stamey's original series reported a cure rate of 93% in 203 patients [37]. Modifications were inevitable and are difficult to identify in the literature—one notable exception is the use of silicone tubing rather than Dacron, to reduce the infection risk [38], inflammatory changes, and stones forming around the nylon threads. Cervigny [39] and Mundy [40] advocated the passage of needles from below to reduce risk of bladder injury. Golomb et al. [41] designed the double pronged ligature carrier to separate the passage of the two needles (Table 70.2).

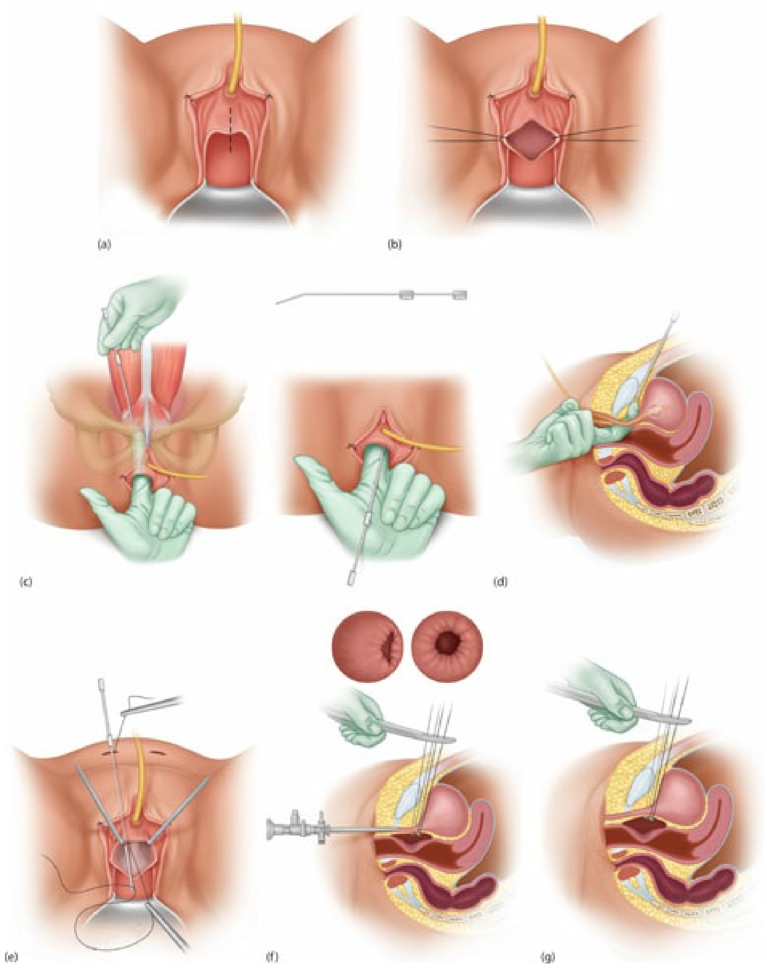

Figure 70.2 Stamey operation: (a) longitudinal vaginal incision, (b) exposure of the bladder neck and paraurethral fascia from below, indicating the points at which the Stamey needles should perforate the paraurethral fascia, (c) the needle can be passed downward to the vaginal incision or, applied to the index finger, from vagina to rectus sheath. This facilitates passage of the nylon suspensory sutures, (d) needle being passed downward onto the tip of surgeon's finger lying alongside bladder neck, (e) positioning of the Dacron cuff, which will support the paraurethral tissues, (f) the bladder neck is checked endoscopically to ensure that sutures do not pass through the bladder and the effect of suture tension on bladder neck closure can be checked, (g) final positioning of the bladder neck after elevation of sutures.

Raz

In 1981, Shlomo Raz described his personal take on the Pereyra operation, which was slightly different to Stamey [42]. His underlying principle was to use the nonabsorbable suture to grasp and bind together the component layers of the endopelvic fascia and to use this to provide support. In essence, his operation was a PVR because it reconstituted the same disrupted fascial layers as that operation (Figure 70.3).

After preparing the patient in a similar way to a Stamey or Pereyra procedure, an inverted U incision is made over the urethra to expose the underlying urethrovesical angle or bladder neck. Dissection then continues—more extensively than with Stamey—to open the endopelvic fascia on either side of the bladder neck. This is achieved by passing the tips of scissors behind the pubic bone, about 2 cm lateral to the urethra, and while keeping the tips in close proximity to the back of the bone, passing them in the direction of the ipsilateral shoulder and then rotating more caudally to pass through the retropubic space to emerge onto the back of the rectus sheath, which is then penetrated. A finger can then be inserted into the defect, though some surgeons prefer to do this using a long handled instrument to minimize tissue disruption.

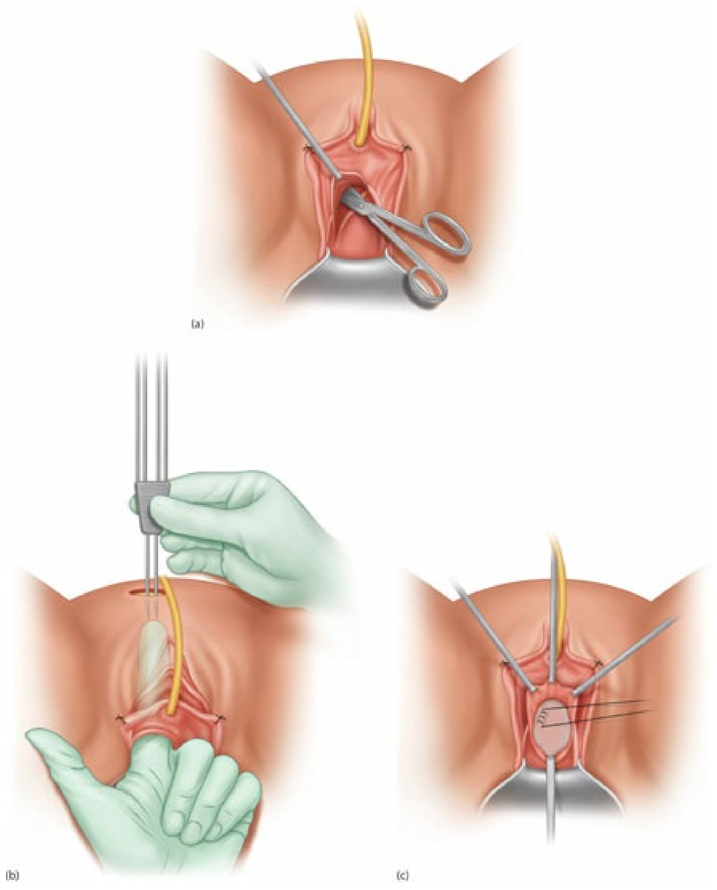

Figure 70.3 Raz cystourethropexy: (a) a lateral dissection of the paraurethral fascia, (b) a finger penetrating the retropubic space from the vaginal incision, and (c) a helical suture is incorporating endopelvic fascia, pubocervical fascia, and subdermal layer of vaginal wall.

The long handled needle is again used from above—passing downward through the retropubic space to reach the examining finger in the paraurethral defect and to pick up a nonabsorbable suture, which is pulled through to the suprapubic stab incision. However, before the second end is pulled through, three helical bites are taken with an attached needle to include three structures: the detached urethropelvic ligament/endopelvic fascia medially, the pubocervical fascia, and the subdermal layers of the vaginal wall. Once this suture is pulled together, the defect in the endopelvic fascia automatically closes and the tissues become elevated alongside the bladder neck.

Endoscopy was not described by Raz, but of course, many who subsequently performed this operation adopted Stamey’s recommendation of cystoscopy along with Raz technique of tissue plication rather than graft insertion.

In his first description of the new technique, he reported 96 of 100 patients cured of SUI [42].

Gittes

Whether the Gittes operation [43] represents a significant modification of these two highly popular operations is unclear—certainly, it never achieved the same degree of popularity. Gittes essentially dispensed with the need for any vaginal dissection by applying the same technique as Raz in terms of needle passage, but with passage of the helical sutures directly through the vaginal wall. His hypothesis was that the paraurethral dissection suggested by Raz was unnecessary—indeed it created a defect that might or might not have already been present only to immediately repair it again. By placing the sutures directly into the vaginal skin, he was securing the same layers, but they would cut through the vaginal skin and become buried in the paraurethral tissues where they would provide support. It is not clear whether the lack of dissection was an advantage or disadvantage in providing tissue of adequate strength to hold the sutures in place (Figure 70.4).

The outcomes from reviewed studies are shown in Table 70.3. Seven RCTs were identified for needle suspensions, making comparisons of needle suspension with the Burch colposuspension [17,40,44–46], anterior repair [17,46], MMK [47], and porcine dermis sling [48]. The evidence suggests that outcomes are inferior to retropubic suspensions (except for one study with poor methodology [47] in which there were more failures for MMK at 12 months) and equivalent to the results of the anterior repair/colporrhaphy. The Cochrane Review [49] on needle suspensions drew this conclusion after commenting that the quality of the studies was poor. More recently, there have been studies comparing transvaginal mesh placement to laparoscopic Burch colposuspension as well as to a combined AC and Burch combination repair showing that the transvaginal mesh repairs in both studies were superior, with sustainable results at long-term follow-up [50,51].

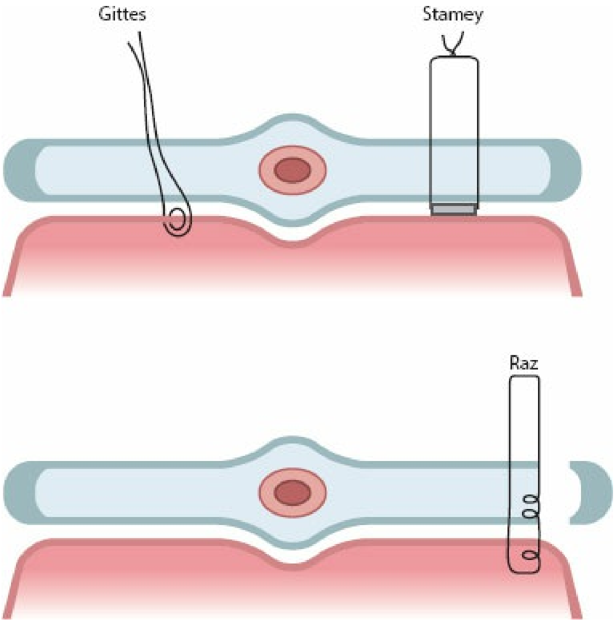

Figure 70.4 Schematic diagram to illustrate the different suture positions of (a) a Gittes suspension (vaginal wall only), (b) Stamey operation (Dacron cuff placed in paraurethral “pocket”), and (c) the Raz cystourethropexy (a 3-0 bite helical suture including pubocervical fascia, endopelvic fascia, and subdermal layer of vaginal wall).

[a] Italics refer to comparator procedures only.

Ten case series or cohort studies for Stamey are reviewed with follow-up ranging from 12 to 90 months [38,48,52–60]. Outcomes are reported with widely differing measures, some objective and other subjective, ranging from 20% objective cure at 2 years to 90% subjective cure at a mean of 38 months. For the series reporting the Raz operation, the range is from 89% subjective cure at 12 months to 47% objective cure at 25 months [61–63]. The subjective cure rates from both the original and modified Pereyra [64–66] and the Gittes operation [67] do seem particularly disappointing. There are little data on the Raz four corner or in situ sling technique [68,69], and it is impossible to say how it compares to other procedures.

The general conclusion about needle suspensions is that the long-term results were disappointing. Those studies that presented outcomes at differing time points [17,46,63] appear to show a greater progressive deterioration with time than for Burch, but this difference does not reach statistical significance, since the event (failure) itself is uncommon. However, if one plots the length of follow-up, in case series, against subjective cure rates, no correlation can be seen. This is most probably because of differing definitions of cure. Urinary retention occurred between 2% and 17%, while de novo urgency was reported in up to 30% of individuals. Postoperative pain has been reported in up to 70% of women, but figures for long-term pain are sparse. Progressive prolapse tends not to have been reported in these series.

BONE ANCHORING

Leach was the first to describe the use of bone anchoring to provide support for the sutures of a needle suspension [70]. He was conscious of the tendency for nonabsorbable sutures used in needle suspensions to cut through tissues and result in failed support and or pain and felt that securing them to the rigid structure of the pubic bone would be more reliable. Benderev [71] in 1992 reported their use in 53 women with no initial complications and few failures.

The concept of being able to sell a bone anchoring device was appealing to the device manufactures, and two devices in particular were introduced. The Vesica system involved a screw, derived from orthopedic surgery, with electric driver that could be driven into the pubic bone through a small suprapubic incision [72]. A Gittes type of suspension was then applied in which the suprapubic needle passage penetrated the vaginal skin several times lateral to the bladder neck to create a Z-shaped configuration.

The other system (in tac) introduced at the same time involved a C-shaped drill device, which, when inserted into the vagina like an upside-down speculum, would drive a screw into the back of the pubic arch [73,74].

As with most new procedures, the initial results were encouraging and devices were enthusiastically employed in many women. However, in 2004 Goldberg reported osteomyelitis of the pubic bone, a serious complication potentially leading to a lifetime of pain and disability, in 3 of 290 women undergoing bone-anchored sling placement [75], after which other similar reports followed. Screw dislodgement also occurred at an unacceptable level [76], and other poor results were reported [77–79]. In 2003, NICE finally recommended that these techniques should be abandoned [80].

FOUR-CORNER VAGINAL PATCH

Raz, in his continued personal quest to find the fail proof operation for stress incontinence, developed a further modification of his earlier operation with the “in situ” vaginal wall sling in 1989 to obviate the need for implanting artificial mesh or indeed for transplanting autologous material from one place to another [81]. In concept, this was really a combination of needle suspension technique and autologous fascial sling.

With the patient in lithotomy position, a four-sided patch was incised in the vaginal wall based at the level of the bladder neck with the narrower edge over the distal urethra (Figure 70.5). Through the lateral margins of this incision, dissection was extended laterally and caudally and into the retropubic space as for a standard Raz procedure, but not underneath the patch. The patch was to be used as the autologous fascia with which to elevate the whole urethra. Four individual sutures were then inserted into the corners of this patch and passed upward through the endopelvic fascial defect by means of a needle carrier and then tied over the rectus sheath in the same manner as previously. Vaginal wall has the potential advantage that it is likely to be more flexible than harvested fascia and hence less likely to cause obstruction.

Initial results again were encouraging—93% of the first 160 women achieved continence at medium-term follow-up [82]. The operation never caught on—presumably because of its perceived difficulty and the concurrent emergence of simple and effective midurethral slings.

SLINGS

Well over 100 years ago, the principle of placing a strip of autologous tissue beneath the urethra to provide an obstructive effect was established. It is never quite clear in retrospect who made the first contribution since one relies entirely on what others have written on the subject. However, undoubtedly the person who popularized the concept of placing RF around the urethra was Aldridge in 1942 [83]. Previous descriptions of surgery had included the use of pyramidalis muscle tendon transplanted to elevate the urethra [84] and the addition of RF and bladder neck plication [85] to this technique. Modifications of this technique were practiced in some centers until fairly recently [86]. The gracilis muscle was also used as early as 1907 [87], and these tendon and muscle, innervated or otherwise, have repeatedly been used over the years to wrap both the urethra and the anorectum, but suffer from the extent of dissection and mobilization required, the bulk of tissue requiring accommodation in the new site, and overall poor results.

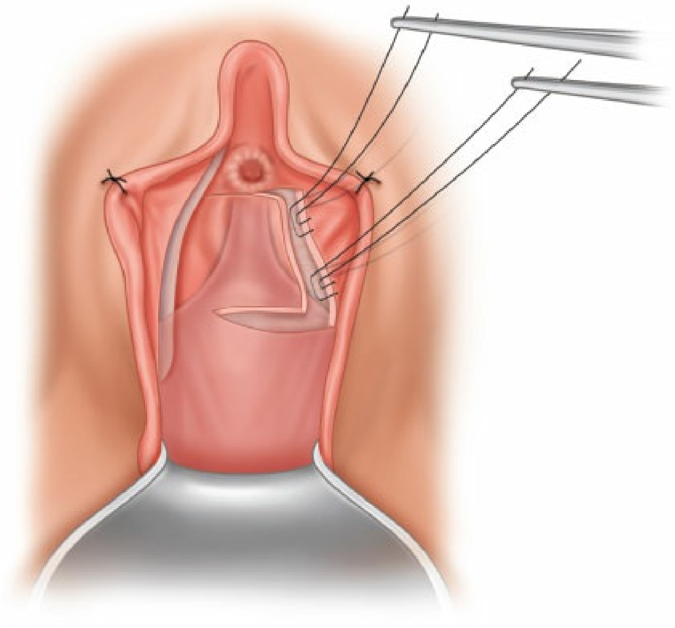

Figure 70.5 Four-corner “in situ” vaginal wall sling. A placard shaped incision is made with its base at the bladder neck and narrow edge distally to expose the paraurethral fascia. Four separate helical sutures are used to gather up the endopelvic fascia, pubocervical fascia, and the subdermal layer of the vaginal wall.

The mechanism of action of sling procedures has always been a subject of debate and uncertainty. Early wrappings with denervated muscle of one kind or another may have simply provided additional passive resistance, but subsequent designs in which slings were passed around the suburethra, at whatever level, and fixed above to an immovable structure, may have offered either passive occlusion during straining or possibly a dynamic component as well. The concept of a dynamic effect is that abdominal straining involves rectus muscle contraction, which will pull upward on the attached sling, thereby elevating the bladder neck for the duration of the contraction.

All slings therefore have the potential to obstruct the urethra or simply to provide passive occlusion during moments of stress. It is a feature of all biological materials, whatever their provenance, to have the potential to shrink/contract by up to 30% of their initial length. Shrinkage of this degree will obviously further elevate the bladder neck or urethra and risk causing voiding difficulty. The tendency may be more marked with some tissues than others, but this has not really been established. Every sling material should have more or less the same effect to begin with, but the specific material used evidently matters in terms of its capacity for shrinkage, infection, erosion, and subsequent stretching or failure, while the amount of tension applied to the sling and its positioning will possibly adversely affect filling and voiding function. Whether slings are inserted from top-down or bottom-up appears to make little difference though there is evidence that the more extensive the vaginal dissection required, the more likely it is that innervation will be disturbed [87].

Aldridge described an operation in which, following a transverse suprapubic incision, two strips of RF were mobilized in the line of the external oblique fibers, detached at their lateral extremities, and left attached to the RF close to the midline. Thus, strips of fascia were created at least 10 cm in length on each side (Figure 70.6). A midline suburethral vaginal incision was then made to expose the pubocervical fascia and dissection continued cranially toward the retropubic space. A midline colporrhaphy was first performed to provide bulking of tissue under the urethra, and the ends of the rectus strips were then passed downward through the retropubic space on each side to emerge into the vaginal incision on either side of the urethra. Here, they were then sewn together under the urethra to provide elevation and support of the urethra.

Of course, in the finest surgical tradition, the procedure has been much modified, a neat idea being that used by Warrell in which dissection of the medial component of the rectus strip was angled downward to create additional length, thereby also reducing the need for lateral dissection (Figure 70.6). Lateral dissection in the original procedure was complicated by the thinness of external oblique fascia beyond the lateral border of the rectus sheath and the risk of lateral angle pain postoperatively.

Leaving the sling attached at one end obviated any need for fixation except under the urethra, but this created difficulties in establishing the correct amount of tension; in addition, there were times when sometimes the sling would not reach the vagina.

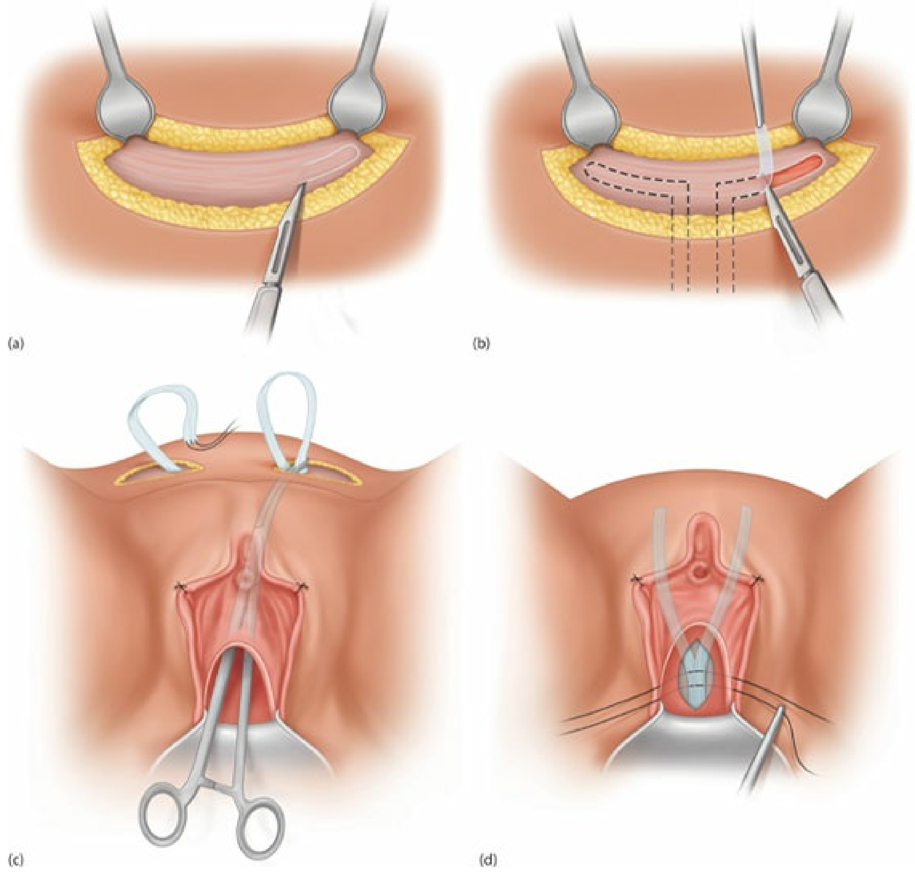

Figure 70.6 The Aldridge sling: (a) four separate fascial strips are mobilized with a medial attachment, (b) Warrell's modification provides extra length, (c) the lateral ends are tunneled down into the paraurethral space by attachment to a long-handled forcep, (d) the lateral ends are sutured together under the proximal urethra—the number and position of sutures will determine the degree of elevation and tension.

In 1978, McGuire reported the use of a free graft of RF, which facilitated adjustment of tension, though it is clear that his intention was to create a significant elevation of the bladder neck [88]. During his dissection of the vaginal end, he deliberately opened the bladder in order to prevent damage to it, a surprising suggestion coming several years after Stamey popularized peroperative endoscopy, in part, for the same reason. Blaivas also reported the use of a free graft [89], and, between them, these two surgeons radically influenced surgical practice throughout the United States over the next 20 years. The reasons for this were the growing awareness of poor long-term outcomes from needle suspensions and that a fascial sling would be effective in women with either hypermobility or intrinsic sphincter weakness or both. It became known that slings with less tension remained effective but with diminished likelihood of postoperative voiding dysfunction, which remained a problem for retropubic suspensions.

Full-Length Autologous Rectus Fascial Sling: Technique

The procedure described is that used throughout the 1990s; inevitably, modifications took place with the adoption of ideas from others and the growing realization that tension should be minimal and the midurethral rather than bladder neck support was the objective (Figure 70.7).

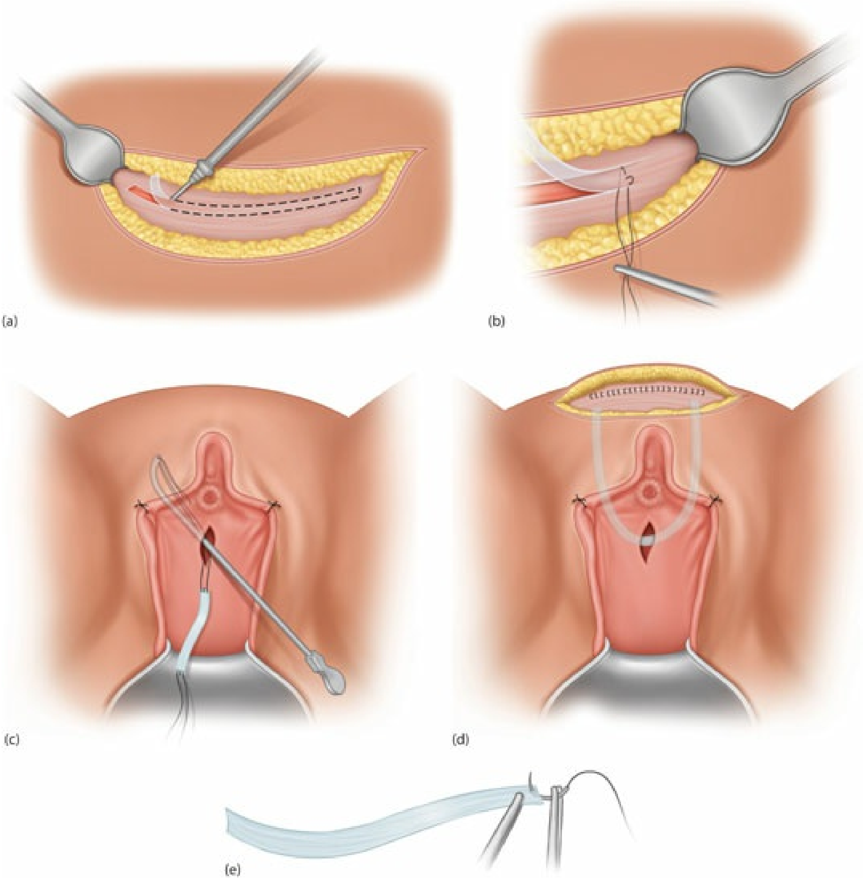

Figure 70.7 Free rectus fascia pubovaginal sling: (a) a free graft is fashioned from the rectus sheath. (b) Before dividing, a suture is placed through the lateral ends of the mobilized sling, (c) a modified Clutton sound is used to pass the suture with sling attached upward through the space of Retzius, (d) the ends of the fascial sling are sutured to the rectus sheath with minimal tension, (e) alternatively, a short length of fascia is used and mounted on nylon sutures to minimize the dissection of the rectus—"sling on a string."

The patient is placed in lithotomy position with the legs flexed to <90°. A degree of Trendelenburg tilt in the operating table provides a good view of the anterior vaginal wall and helps to autoretract any abdominal fat apron. Particularly, fatty labia may be temporarily gently sutured laterally to provide a good vaginal view. The bladder is catheterized, following which the anterior vaginal wall infiltrated with 1:200,000 epinephrine in saline solution. This may then be left for a few minutes while the abdominal dissection takes place (Table 70.4).

A transverse suprapubic incision is made down to the RF, and two parallel transverse incisions commenced in the rectus about 2 cm apart—these are extended laterally with scissors in the line of the fibers of rectus and external oblique—that is, angling upward. This dissection can easily provide 20–25 cm of fascia. Laterally, the fascia divides into two layers. Before dividing the fascial strip laterally, a transfixion suture of 2-0 nonabsorbable material is used to bind the tissues together. The fascia is then divided obliquely rather than at 90° so that the initial repair stitches will not cause too much tethering in the lateral angles—the probable cause of postoperative lateral angle pain. The fascial strip, which has been separated, is stripped of any attached fat and then wrapped in a saline-soaked swab for later use. The fascial defect is first undermined for a few centimeters with scissors and then repaired with multiple 2-0 nonabsorbable sutures applied at right angles to the cut edge of the fascia, thus ensuring proper alignment of the repair. The use of multiple small sutures spreads tension effectively and minimizes the risk of tearing, which will occur with larger, less frequent stitches.

[a] Italics refer to comparator procedures only.

Attention is then returned to the vagina, and a 2-cm midline incision is made over the midurethra. The edge of the incision is lifted with strong toothed forceps and dissection commenced with Metzenbaum scissors, angled with the concave curve facing the surgeon, to create a tunnel toward the pubic arch. On making contact with the pubic arch, the scissors are turned so that they point toward the ipsilateral shoulder and gently advanced behind the pubic arch by a spreading motion in order to penetrate the endopelvic fascia and enter the retropubic space. The same dissection is then carried out on the other side. Despite the use of epinephrine infiltration, there are numerous tenuous veins applied to the endopelvic fascia, which can easily be ruptured by this dissection, and, consequently, at this point, bleeding can appear to be copious. This will almost always settle as the operation proceeds.

The sling can now be inserted into the tunnels on either side of the urethra. This can be done by using a long-handled Roberts forceps either passed upward with the sling attached using the previously applied sutures. The sound is then passed into the previously created tunnel on either side of the urethra and upward through the retropubic space to push through the back of the RF and emerge into the suprapubic wound a couple of centimeters caudal to the previous repair. The sling is then adjusted so that it lies comfortably under the midurethra and can be fixed into place using four 4-0 absorbable sutures to avoid curling or displacement of the sling. The free ends of the sling protruding through the RF can then be sutured into place using a nonabsorbable suture. For many years, this was done in such a way as to cause the urethral end of the sling to just begin to move cranially. An instrument can be placed between the sling, and the urethra as the slack is taken up or a cystoscope can be placed within the urethra at this point to ensure correct tensioning. Cystoscopy is also usually performed to ensure that no bladder injury has occurred and also to check the position of the sling in relation to the urethra. For this procedure, on account of the necessarily extensive suprapubic dissection, a suprapubic catheter would typically be placed and delay a trail of voiding for at least 48 hours; however, this has often been abandoned in recent years.

Fascia Lata

A disadvantage with RF is its varying thickness and length, and to overcome this problem, the use of host fascia lata was described. In this operation, the patient is first placed in a full lateral position and a line drawn on the skin between the greater trochanter and the lateral condyle of the femur (the external markings of tensor fascia lata). A series of two or three small transverse incisions are made over this line and dissected down onto the muscular fascia. Using these small incisions for access, two parallel longitudinal incisions are made into the fascia lata, 1.5–2 cm apart and extended with dissecting scissors (Figure 70.8). By performing the same technique in two or three sites, a length of up to 20 of fascia can be mobilized and separated from its ends. The resultant defect does not widen (as is the case with the RF defect) and so does not need to be closed. However, pain and hematoma can still occur so a small suction drain should be placed.

The patient is then placed in the standard lithotomy position, and the sling is inserted around the urethra through a combination of suburethral and suprapubic incisions and fixed either to itself over the rectus sheath or alternatively to the rectus sheath itself (Figure 70.7).

The way in which autologous sling surgery is performed has matured gradually over the years, and it is a little contrived to suggest that all slings done before a certain date should be consigned to history. Nevertheless, for this chapter only, those slings that could be identified to be full-length fascial strips are reviewed—shorter supported slings are left out. However, the precise positioning and varying degrees of tension are impossible to classify by review, and so the evidence presented is a somewhat selective view of the evidence.
